Background: Melittin, the main active peptide ingredient of bee venom, can cause severe cell membrane lysis due to its robust interaction with negatively charged phospholipids. So far, no effective anti-melittin vaccine has been developed to protect people from undesired melittin intoxication.

Methods: Herein, we prepared a polydiacetylene (PDA) nanoparticle with cell membrane-mimic surface to complex melittin, forming an anti-melittin vaccine (PDA-melittin).

Results: PDA nanoparticles could effectively combine with melittin and neutralize its toxicity. PDA-melittin nanocomplex is demonstrated to enhance melittin uptake by DCs and stimulate strong melittin-specific immunity. Mice immunized with PDA-melittin nanocomplex showed higher survival rate after exposure to melittin than untreated mice.

Conclusion: The PDA-melittin nanocomplex can efficiently and safely generate a specific immunity against melittin to protect body from melittin intoxication, providing a new method with potential clinical application for the treatment of melittin intoxication.

Keywords: PDA nanoparticles, melittin, toxoid vaccine, immunity

Introduction

Pore-forming toxins (PFTs) are membrane-damaging proteins secreted by bacteria and wild living creatures (e.g., snakes, scorpions and wasps).^{1,2} Melittin is an important PFT and the main active component of venom peptides. It can lyse cell membranes by inhibiting transport pumps, particularly H⁺/K⁺-ATPase and Na⁺/K⁺-ATPase.³ This leads to significant morphological change and functional damage, especially in excitable tissues like nerves and glands. Additionally, the membrane disruption mechanism of melittin also depends strongly on the geometry of the lipid layer. Lateral phase separation and lipid heterogeneity play a crucial role in the membrane disrupting process of melittin.⁴ Melittin showed stronger spontaneous activity on heterogeneous raft-forming membranes compared with homogeneous non-raft forming membranes with the same amount of cholesterol, which provides a basis for the design of antimicrobial peptides.

Current strategies of treating toxoid intoxication basically rely on toxoid vaccine that processed with chemical or physical inactivation.^{5,6} Application of these strategies is restricted by the latent disruption of the epitope.^{7,8} Therefore, how to preserve the immunity epitope of melittin while eliminating its toxicity is a big challenge in the preparation of anti-melittin vaccines. In previous research on toxoid vaccine, erythrocyte membrane was separated to initiate nanoparticles which could entrap PFTs without compromising the structural integrity of toxins.⁹ The in vivo result shows that vaccination with nanoparticle-detained toxin stimulates stronger protective immunity against

toxins compared with heat-denatured toxin vaccination. However, the potential immunogenicity risk is the greatest challenge when using exogenous erythrocyte membrane to form a toxin vaccine. Recently, researchers prepared a variety of multi-functional polymer nanoparticles with high affinity to toxin, reaching up to 100% neutralization efficiency.¹⁰ This research provided a new approach for designing advanced plasticity antidote. Based on our previous research, we found through computer simulation that nine conformations of negative binding affinities were obtained after docking polydiacetylene (PDA) nanoparticles to melittin.¹¹ We concluded that PDA nanoparticles had the ability to interact with melittin through hydrophobic and electrostatic force, which further demonstrated that PDA nanoparticles could theoretically capture melittin. Since PDA nanoparticles are synthetic polymers without a non-immune prototype, they may overcome the risk of immunogenicity.

10,12-Pentacosadiynoic acid (PCDA) is the diacetylene monomer used for preparation of PDA nanoparticles.^{12,13} After ultraviolet irradiation, the diacetylene monomer will form ene-yne alternating polymer chains, which are responsible for the sensitivity of PDA nanoparticles to environmental changes, such as temperature variation, solvent changes, vapor exposure and pH variation, showing corresponding color change (blue to red) and emissive activation.^{14–16} The obtained PDA nanoparticles with specific vesicle structure are capable of sensing, attracting and neutralizing PFTs without causing protein denaturation, mimicking the role of normal cell membranes.^{17,18}

In our study, we prepared a PDA–melittin complex to enhance immunity against melittin by incubation with PDA nanoparticles. PDA nanoparticles were characterized by size, zeta-potential, morphology, blood stability and toxin-binding efficiency. Furthermore, the antitoxin ability of the PDA–melittin complex vaccine against melittin was evaluated both *in vitro* and *in vivo*. We thus designed a biomimetic PDA nanoparticle based PFT antigen delivery platform. The platform consisted of analogous cell membrane mimic nanoparticles for the delivery of the perforation toxoid group, which could inspire the development of a broad-spectrum antitoxin vaccine and show potential application in PFT detoxification.

Materials and methods

Materials

Melittin, 10, 12-pentacosadiynoic acid (PCDA), MTT reagent, bovine serum albumin (BSA), 4',6-diamidino-2-phenylindole (DAPI) and coumarin were purchased from Sigma-Aldrich (St Louis, MO, USA). CD40-PE, Major

Histocompatibility Complex Class II (MHCII)-APC, CD80-fluorescein isothiocyanate (FITC) and CD11c-PE antibodies (mouse) were purchased from Miltenyi Biotec (Bergisch Gladbach, Germany). Interleukin 4 (IL-4) and granulocyte-macrophage colony stimulating factor (GM-CSF) were purchased from Bio-legend (San Diego, CA, USA). 3,3',5,5'-Tetramethylbenzidine (TMB) substrate was purchased from Beyotime Biotechnology (Shanghai, People's Republic of China). Goat anti-mouse IgG (H+L), fetal bovine serum (FBS), Roswell Park Memorial Institute 1640 (RPMI-1640) and penicillin-streptomycin were purchased from Thermo Fisher Scientific (Waltham, MA, USA). All solvents used in this study were above analytical grade.

Cell line and mice

The 3T3 fibroblast cell line was purchased from American Type Culture Collection (ATCC, Manassas, VA, USA) and cultured in RPMI-1640 medium with 10% fetal bovine serum, 100 U/mL penicillin, 100 µg/mL streptomycin, 400 µg/mL G418 and cultivated in an incubator at 37°C with 5% CO₂ atmosphere. All animals were purchased from Beijing HFK Bioscience (Beijing, People's Republic of China) and raised under pathogen-free conditions. Mice were habituated to the environment for at least two weeks before the experiment. Six- to eight-week-old female C57BL/6 mice were used to extract bone marrow cells and cultivate bone marrow derived dendritic cells (DCs). Six- to eight-week old female BALB/c mice were used to perform the immunoprophylaxis and immunotherapy studies of PDA–melittin against toxins. Mice were humanely treated according to the guidelines of the Institutional Animal Care and Treatment Committee of Sichuan University. All animal procedures were approved and controlled by the Institutional Animal Care and Treatment Committee of Sichuan University.

Preparation of PDA nanoparticles

To prepare polymerized nanoparticles, 12 mg of PCDA was dissolved into dichloromethane and then filtered through a syringe filter (organic system; pore size 0.22 µm) (Millex-LG; EMD Millipore, Billerica, MA, USA) to purify the monomers before use. The filter liquor was put under rotary evaporation at 45°C for 30 min to remove the dichloromethane completely. Four mL double-distilled water at 60°C were added to re-dissolve the precipitate, followed by probe sonication for 15 min at ~75°C, then stored overnight at 4°C. At last, the nanoparticles were crosslinked by irradiation with ultraviolet for 45 min at room temperature. The obtained solution was adjusted to 2 mg/mL with water and stored at 4°C.

Structural analysis of PDA nanoparticles

Size distribution, average size and zeta potential were determined by Zetasizer Nano ZS (Malvern Instruments, Malvern, UK). The PDA nanoparticle solution was diluted to a suitable concentration, and the size and zeta potential of PDA nanoparticles were tested at 25°C after equilibration for 2 min. The PDA nanoparticles were dyed with phosphotungstic acid and their morphology was examined by a transmission electron microscope (H-6009IV; Hitachi Ltd., Tokyo, Japan).

Interaction between PDA nanoparticles and melittin

Neutralization efficiency of PDA nanoparticles to melittin was measured by a red blood cell (RBC) lysis test. Fifty μL melittin (10 $\mu\text{g}/\text{mL}$) were pre-incubated with same volume of PDA nanoparticles (PBS as solvent). The PDA/melittin mixture, free melittin (5 $\mu\text{g}/\text{mL}$, 100 μL) and PBS were then incubated with 100 μL murine RBC solution (4%) for 30 min at 37°C. Samples were then centrifuged at 2,000 rpm for 1 min. Release of hemoglobin was monitored by measuring the absorbance (A_{sample}) of the supernatant at 540 nm. Controls for 0 and 100% neutralization of hemolytic activity consisted of RBCs incubated with 5 $\mu\text{g}/\text{mL}$ melittin ($A_{0\%}$) and PBS ($A_{100\%}$) respectively. The percentage of neutralization was calculated according to Equation 1:

$$\text{Neutralization efficiency (\%)} = 100 - \frac{A_{\text{sample}} - A_{100\%}}{A_{0\%} - A_{100\%}} \times 100 \quad (1)$$

The intensity of red fluorescence emitted by the toxin-bound PDA nanoparticles was measured over time. Then 100 μL melittin (0.1 mg/mL) were added into 100 μL PDA nanoparticles (1 mg/mL) (PBS as a solvent), and the red fluorescence intensity of the mixture was analyzed under a fluorescence microscope at different time points.

A drug release study was used to detect the release curve of melittin from PDA–melittin complex. Melittin was mixed with PDA nanoparticles at mass ratio of PDA:melittin=10:1 in deionized water. The mixture was then dialyzed in PBS using a dialysis bag (molecular cutoff weight is 80–120 kDa). Free melittin released from the PDA–melittin complex in the dialysate was collected at different time points, then the content was measured by high performance liquid chromatography (Zenix-C SEC-150, Sepax Technologies, Inc., Newark, DE, USA, 4.6 \times 300 mm column, PBS as liquid phase, pH=7.0, flow rate=1.0 mL/min, detection wavelength is 210 nm). The one-point external standard method was applied to calculate the content of melittin according to Equation 2:

$$C_x = C_r \times \frac{A_x}{A_r} \quad (2)$$

where C_x = sample concentration; C_r = standard substance concentration; A_x = peak area of sample; A_r = peak area of standard substance.

The percentage of release was calculated according to Equation 3:

$$\text{Release rate (\%)} = \frac{C_n \times [V_2 - (n-1)V_1] + (C_{n-1} + \dots + C_2 + C_1) \times V_1}{n} \times 100 \quad (3)$$

where n = time of sample collection; c = concentration of collected sample; v = volume of collected sample.

Generation of murine bone-marrow-derived DCs

The bone marrow was obtained from female C57BL/6 mice aged 6 weeks. After repeated blowing of the cell suspension to disintegrate clusters, the RBC lysis buffer was added to remove RBCs from the suspension. After washing with RPMI-1640 medium twice, the cells were resuspended in RPMI-1640 medium containing GM-CSF (10 ng/mL) and IL-4 (10 ng/mL). After 48-h cultivation at 37°C with 5% CO_2 atmosphere, the cell supernatant was discarded and the precipitated cells were collected and resuspended with fresh medium, cultured in 6-well plates. The medium was totally replaced with fresh medium after 48 h. Then half the medium was refreshed every 2 days with cytokines of appropriate concentration added. Six days later, all the suspended cells were collected to obtain rich bone marrow-derived DCs.

In vitro cytotoxicity assay

To evaluate the cytotoxicity of PDA–melittin complex, the cellular viability of DCs and murine 3T3 cells were detected using an MTT assay. 3T3 cells and bone marrow derived DCs were planted in a 96-well plate (5 \times 10⁴ cells/well) separately and then cultivated in an incubator overnight. When the cell density reached 60%, 100 μL PDA–melittin complex solution (3T3 cells, mass ratio PDA:melittin=10:1, the concentration of melittin is 6.25, 12.5, 25, 50, 100 $\mu\text{g}/\text{mL}$, respectively; DCs, mass ratio PDA:melittin=10:1, the concentration of melittin is 12.5 $\mu\text{g}/\text{mL}$) was added per well and incubated for 24 h. Then 0.5% MTT was added, followed by incubation for 4 h under the same conditions. After removing the supernatant, 150 μL DMSO was added into the well and then the plate was shaken at low speed on a shaker to dissolve the

crystals completely. The OD value ($\lambda=570$ nm) of sample (OD_{sample}) and control (OD_{blank}) was detected and cellular viability was calculated according to Equation 4:

$$\text{Cell viability (\%)} = \frac{OD_{\text{sample}} - OD_{\text{blank}}}{OD_{\text{control}} - OD_{\text{blank}}} \times 100 \quad (4)$$

Cellular uptake of PDA–melittin complex to DCs in vivo and in vitro

Cellular uptake of PDA–melittin complex in vitro could be evaluated by detecting the red fluorescence emitted from PDA–melittin nanocomplex in DC cytoplasm. For this, 500 μL (12.5 $\mu\text{g}/\text{mL}$) melittin was incubated with the same volume of PDA nanoparticles (initial concentration is 125 $\mu\text{g}/\text{mL}$) for 30 min. Then the mixture (1 mL) was added to the DCs (1×10^4 cells/well) at 37°C with 5% CO_2 atmosphere for 1 h. Then the cells were dyed with DAPI (0.1 $\mu\text{g}/\text{mL}$) and the cellular uptake of PDA–melittin complex was observed under a fluorescence microscope. Furthermore, the PDA nanoparticles which were labeled with coumarin were subcutaneously injected into mouse. After 24 h, the draining lymph nodes at the injection site were taken out, completely ground and filtered to obtain a cell suspension. Then the obtained cells were marked with CD11c-PE antibodies and flow cytometry was used to test uptake efficiency of PDA nanoparticles by DCs in vivo.

DCs maturation analysis

DCs at day 6 (3×10^5 cells/well, 12-well plate) were incubated with PDA–melittin complex loaded with 1.25 μg melittin at 37°C for 24 h in incubator. Three surface antigen markers (PE-CD40, APC-MHCII and FITC-CD80) level was measured by flow cytometry (BD Biosciences, San Jose, CA, USA) and analyzed by FlowJo software Version 6 (TreeStar; Becton, Dickinson and Company, Franklin Lakes, NJ, USA).

Immune protection analysis

BALB/c mice (6–8 weeks old, female) were immunized with PDA–melittin complex (0.5 mg/kg melittin, PDA:melittin=10:1) every other week, three times in total ($n=10$). Then the serum samples were collected at different time points. Enzyme linked immunosorbent assay (ELISA) was used to measure the IgG titers of anti-melittin specific antibodies. Then, a RBC lysis test was administrated to evaluate the neutralization rate of serum obtained from mice vaccinated after 28 days. The immunized mice received a lethal bolus dose of melittin at 3 mg/kg through intravenous tail-vein injection and the protective immunity against

melittin was examined by the observation of survival rate over time.

Results

In this work, we developed a method of preparing PDA nanoparticles with appropriate size and uniform distribution. The formation process is presented in Figure 1A. We used the diacetylene monomer PCDA to self-assemble the spherical bilayer structure by probe sonication. The 1,4-photopolymerization activated by ultraviolet irradiation would form a π -conjugated backbone with alternating double- and triple-bond groups in the main polymer chain, which leads the polymer to have a deep blue color.¹¹ The morphology analysis of the PDA nanoparticles was performed via transmission electron microscope. The size and zeta potential of PDA nanoparticles were also measured by Zetasizer Nano ZS. The equilibration time was 2 min and test temperature was 25°C during measurements. All results were expressed by the means of three test runs plus standard error. As shown in Figure 1B, the PDA nanoparticle prepared in our experiment presented a vesicle structure in the images of TEM and had an average diameter of about 70 nm (PDI=0.231) with a zeta potential of $-30 \text{ mV} \pm 1.2 \text{ mV}$ on its membrane (Figure 1D and E). The average diameter of PDA–melittin nanoparticle is 81 nm (PDI=0.271) and the zeta potential is $-17 \text{ mV} \pm 0.8 \text{ mV}$ (Figure 1F and G). The absorption spectra of PDA nanoparticles containing a peak with a maximum at 650 nm could be observed (Figure 1C).

The interaction between PDA nanoparticles and melittin disrupts the extensively delocalized ene-yne backbones of molecularly ordered PDA side chains, thus causing a colorimetric response from this PDA material and inducing a fluorescence enhancement (Figure 2A). As shown in Figure 2B, binding melittin to PDA nanoparticles enhanced a red fluorescence and the fluorescence intensity gradually increased as the time of combination extended. As shown in Figure 2C, a higher concentration of melittin mixed with PDA nanoparticles could also lead to an increase of red fluorescence intensity. To evaluate the efficiency of PDA nanoparticles to neutralize melittin, we designed a RBC lysis test. In our test, the mixture of PDA and melittin was added into a 4% RBC solution. The melittin neutralization rates of PDA nanoparticles at different concentrations are shown in Figure 2D; observation of the supernatant can also indicate the neutralizing efficacy of PDA nanoparticles (Figure 2E). Based on these results, we concluded that the neutralization efficiency of PDA nanoparticles could reach up to 90% under the mass ratio of PDA:melittin=10:1.

So we adopted this ratio and concentration as alternative criteria in our experiment. A drug release study demonstrated that melittin was firmly captured onto the PDA nanoparticles. We dialyzed the PDA–melittin complex or free melittin solution against phosphate-buffered saline (PBS) and collected the dialysate at eight time-points, using high performance liquid chromatography (HPLC) to determine the toxin release of both samples. As exhibited in Figure 2F, a fast growth phase of the release of toxin was observed within 1 h, followed by a

relatively stable phase. The free melittin sample released the toxin rapidly through the semipermeable membrane and the toxin release rate reached 100% in about 8 h. However, the release rate of the PDA–melittin sample was under 20% within 24 h, indicating that the combination between PDA nanoparticles and melittin is tight.

It is necessary to evaluate the toxicity of PDA–melittin complex for the application of toxoid vaccine. An MTT assay was used to evaluate the cytotoxicity of PDA–melittin

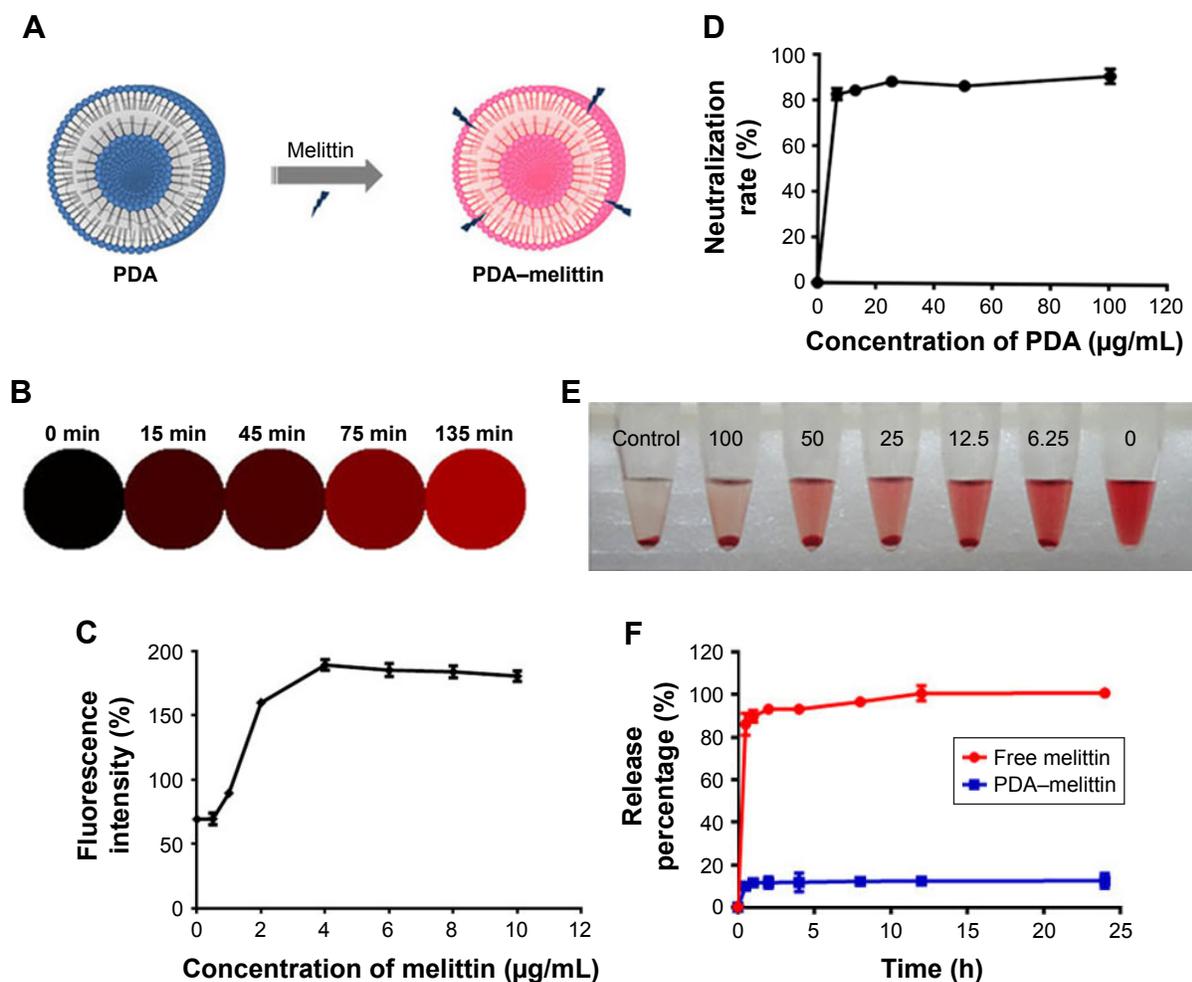

Figure 2 Interaction between PDA nanoparticles and melittin.

complex to mouse 3T3 fibroblast or DCs in vitro. As shown in Figure 3B, PDA could neutralize melittin (initial concentration is 12.5 µg/mL) efficiently and the toxicity of PDA-melittin complex to normal cells was much weaker than free melittin. PDA-melittin complex showed up to 70% cellular viability of DCs, whereas free melittin caused 90% cell apoptosis (Figure 3C), which implied a potential detoxification application in vivo.

The cellular uptake of nanoparticles by macrophages from the mononuclear phagocyte system indicated that the PDA nanoparticle could deliver melittin into antigen-presenting cells as a carrier. We incubated the PDA-melittin complex with DCs and then examined the cellular uptake of PDA nanoparticles by DCs under a fluorescence microscope. As shown in Figure 3A, the red fluorescence appeared in the cytoplasm of DCs, implying that DCs could completely

uptake PDA-melittin complex in vitro. To prove that PDA nanoparticles could target DCs as a carrier in vivo, two groups of mice were subcutaneously injected with PBS (as a control) or PDA nanoparticles labeled by coumarin (green fluorescent). After 24 h, the draining lymph nodes of the mice injection sites were obtained to extract DCs. DCs from the lymph nodes were marked with CD11c-PE antibodies and tested by flow cytometry. As shown in Figure 4A and B, much higher green fluorescence appeared in DCs from mice injected with PDA nanoparticles compared to the control, indicating that DCs could uptake PDA nanoparticles effectively. In addition, it was demonstrated that the PDA-melittin complex could target DCs efficiently. The mechanism of the PDA-melittin complex in promoting immunity against melittin was studied by detecting the specific cell surface antigen expression of DCs. The

MHCII, CD40 and CD80, which were closely related to DC maturation, were marked with fluorochrome-antibody and the expression level was detected by flow cytometry. As shown in Figure 3D, after a 24-h incubation of DCs and PDA-melittin complex in vitro, the DCs showed much higher fluorescence intensity in MHCII, CD40 and CD80 surface antigen than untreated DCs. This suggested that PDA-melittin complex could contribute to the maturation of DCs to achieve better effect of its antigen presentation, further enhancing immunity.

To further illustrate the immunity effect against toxin activated by PDA-melittin complex, we conducted a time-course

study over 92 days and applied ELISA to examine the specific antibody titers of serum from mice. Mice were divided into three groups and immunized with PDA-melittin complex, heated melittin and free melittin respectively (3 immunizations, interval of each time is 7 days). As shown in Figure 4C, the IgG titer level of PDA-melittin complex could reach the peak value (3.2×10^4) at day 28 after immunization, which was higher than those treated with heated melittin and free melittin. IgG titers of all groups reduced over time. The PDA-melittin complex group maintained a higher titer compared with the free melittin group, which gradually lost the protective immunity against melittin. The

efficient antigen delivering effect of PDA nanoparticles to the lymphatic system could cause higher specific antibody titers and improve immunological effect. Furthermore, we conducted a RBC lysis test to evaluate the neutralization rate of the serum obtained from mice vaccinated after 28 days. Melittin was mixed with the serum under different ratios and then incubated with murine RBCs for 30 min. In Figure 4D and E, we found that the hemolytic activity

of melittin reduced with the increase of the serum. When the ratio of melittin:serum=1:2.5 (melittin=1 μg), the serum could completely neutralize the toxicity of melittin. This illustrated that the serum from the vaccinated mice contained anti-melittin substances which were able to produce effective resistance to melittin.

Finally, we examined the protective immune effect stimulated by PDA-melittin complex. At the fourth week,

following 3 doses of vaccination, the mice received a toxin challenge of lethal bolus dose (melittin=3 mg/kg) through intravenous tail-vein injection. As shown in Figure 4F, the survival rate of the unvaccinated group decreased to 20% within 24 h after the injection of melittin, while 75% immunized mice survived under the same condition. The result showed that PDA–melittin vaccine could activate an effective immune prevention.

Discussion

Nanotoxoid strategy shows great promise in preparation of PFT vaccines. Compared with traditional chemical- and heat-mediated detoxification process,^{19–21} toxicity of PFTs is removed in a more moderate and effective way based on the interaction between PFTs and PDA nanoparticles. The PFTs captured by nanoparticles will be specifically and efficiently delivered to DCs. The preserved antigenic epitope on the toxin will effectively stimulate subsequent immunity. This method of antigen protection is supported by the existing application of biomimetic nanosponges in cargo delivery.^{22–24} Inspired by absorption of PDA nanoparticles to PFTs, we prepared PDA nanoparticles and demonstrated that the PDA–PFT complex is nontoxic and can induce antigen-specific protective immunity *in vivo*.

In previous research, we prepared PDA nanoparticles by ultraviolet irradiation of PCDA nanovesicles.¹¹ PDA nanoparticles with vesicle structure and membrane-mimicking surface were used to attract, capture and neutralize melittin. The detoxification process is similar to that of the RBC membrane-coated nanoparticle system, which is reported before.⁹ However, compared with exogenous erythrocyte membranes, it is a reliable way to obtain an antidote without potential immunogenicity risks. Therefore, we explored the application of PDA nanoparticles in antitoxin vaccine in this research. The ene-yne alternating structure of the surface of PDA nanoparticles increases thermal stability and mechanical strength of the materials, indicating promising applications of the nanoparticles in bio-sensing.^{25–27} This is helpful to test the cellular internalization by DCs to PDA–PFT complexes. We incubated PDA nanoparticles with melittin, which is a model toxin, to evaluate the safety of a PDA–PFT complex by the RBC lysis test and drug release study. When we study the toxin releasing state *in vitro*, stimulus-responsive nanoparticles may be useful for constructing a biomimetic membrane model. As reported in previous research,²⁸ hybrid liposomes formed by a photo-polymerizable lipid and saturated lipids go through a phase transition in a relevant temperature

range, which provides possibilities for mimicking the varied conditions of the body microenvironment. Additionally, the uptake of PDA–melittin complex to DCs *in vitro* was observed under a fluorescence microscope. The uptake of DCs to PDA nanoparticles *in vivo* was tested by flow cytometry. All the results indicate that PDA nanoparticles might be safe and effective carriers to achieve toxoid vaccine delivery.

Based on the innate function of regulating immunity induction and tolerance maintenance, DCs are considered critical in underlying the body immune system.^{29–32} Both fluorescence tracking and flow cytometry test demonstrate the enhanced cellular uptake of PDA–melittin complex to DCs compared with the control groups. CD80 is the co-stimulus factor of CD86 in the process of T lymphocyte activation. Irritation of CD40 can upregulate the expression of MHCII, CD86 and CD80 on the cell surface of DCs and enhance the antigen-presenting effect of DCs effectively.³³ In our study, the expression of CD80, CD40 and MHCII on the surface of DCs is increased after immunization by PDA–melittin complex, implying that PDA–melittin can promote DC maturation and enhance its antigen presenting. In the ELISA test, the ability of PDA–melittin complex to elicit specific antibody was evaluated. Meanwhile, PDA–melittin complex immunized mice had the capacity to survive after the challenge of a lethal bolus dose of melittin *in vivo*. No adjuvant was used in this study.

We conclude that PDA nanoparticle-mediated toxin antigen delivery could induce effective immune response and produce toxin-specific antibodies. Thus, PDA nanoparticle-mediated toxin antigen delivery has promising applications in the preparation of broad-spectrum antitoxin vaccine. This strategy provides a theoretical basis and technical guide for achieving different kinds of PFT vaccines, such as α -hemolysin (Hla- α), and aerolysin. Since field work people are much easier to get to perforins, the practical application of these potential products is mainly in beekeeping, snake farming, military affairs, etc. People employed in these occupations could receive related toxin vaccines first for protection from unexpected detoxification.

International Journal of Nanomedicine

Dovepress

Publish your work in this journal

The International Journal of Nanomedicine is an international, peer-reviewed journal focusing on the application of nanotechnology in diagnostics, therapeutics, and drug delivery systems throughout the biomedical field. This journal is indexed on PubMed Central, MedLine, CAS, SciSearch®, Current Contents®/Clinical Medicine,

Journal Citation Reports/Science Edition, EMBase, Scopus and the Elsevier Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <http://www.dovepress.com/international-journal-of-nanomedicine-journal>
