

# Dasatinib: the emerging evidence of its potential in the treatment of chronic myeloid leukemia

Sonya Haslam

Core Medical Publishing, Knutsford, UK

## Abstract

**Introduction:** Current therapy options for chronic myeloid leukemia (CML) include conventional chemotherapy, allogeneic stem cell transplant, interferon-alfa, and imatinib mesylate, which has recently achieved gold standard status. Although the majority of patients initially respond well to treatment with imatinib, wider clinical experience with this drug has resulted in the development of imatinib resistance being increasingly documented. There is therefore an unmet medical need for novel therapies to override imatinib resistance in CML.

**Aims:** This review summarizes the emerging evidence for the potential use of dasatinib in the treatment of imatinib-resistant CML.

**Disease and treatment:** Dasatinib is a novel small molecule that has shown potent antileukemic activity in imatinib-resistant cell lines, malignant marrow cells isolated from patients with imatinib-resistant CML, and in mouse xenograft models of imatinib-resistant CML. Preliminary data from an initial phase I dose escalation trial have been encouraging, indicating that dasatinib is generally well tolerated and produces hematologic and cytogenetic responses in patients with imatinib-resistant CML in all phases of the disease. The maximum tolerated dose (MTD) has not yet been reached, and dose escalation continues to determine the dose range that yields optimal results.

**Profile:** Although dasatinib is still in the early stages of development, the potential impact of this molecule on the treatment of CML could be revolutionary, not only providing a much needed treatment option for patients with imatinib-resistant CML, but also, combined with imatinib, could possibly prove useful in delaying the onset of resistance to treatment. Furthermore, combined with other agents active in CML, dasatinib could have potential utility in purging residual leukemic cells in patients whose disease is controlled by imatinib.

**Key words:** dasatinib, BMS-354825, BCR-ABL, SRC-ABL kinase inhibitor, chronic myeloid leukemia (CML), imatinib resistance, treatment, evidence, outcomes

## Core emerging evidence summary for dasatinib in imatinib-resistant chronic myeloid leukemia

Outcome measure	Emerging evidence
Hematologic response	Achieved in the majority of patients, regardless of stage of disease
Cytogenetic response	Achieved in substantial numbers of patients, even though the optimal dose has not yet been determined
Molecular response	1–2 log reduction in BCR-ABL transcripts associated with major cytogenetic responses in patients with chronic phase CML

## Scope, aims, and objectives

Dasatinib (BMS-354825; Bristol-Myers Squibb) is a small molecule investigational drug, which is currently in phase I development to override imatinib resistance in chronic myeloid leukemia (CML). This review summarizes the disease background, current therapy options, and unmet medical needs, and examines the emerging evidence for the potential use of dasatinib in the treatment of imatinib-resistant CML.

## Methods

The English language medical literature was searched on February 8, 2005 in the following databases:

- PubMed, <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi>
- EMBASE, <http://www.datastarweb.com>
- Database of Abstracts of Reviews of Effectiveness (DARE), NHS Economic Evaluations Database (NHSEED), Health Technology Assessment (HTA), <http://www.york.ac.uk/inst/crd/darehp.htm> (all fields searched in all three databases together)
- NHS HTA, <http://www.nchta.org>
- National Guideline Clearing House, <http://www.guideline.gov>
- Cochrane Database of Systematic Reviews (CDSR), <http://cochrane.org/index0.htm>
- Clinical Evidence (BMJ), <http://www.clinicalevidence.com>
- EBM reviews (ACP Journal Club), <http://www.acpjic.org>

The search terms used were “BMS-354825” OR “BMS354825”, and the cut-off dates were from the beginning of the database to the date of the search.

A total of six articles were identified: three preclinical articles, and three editorial/opinion articles. No relevant systematic reviews or treatment guidelines involving dasatinib were identified.

The proceedings of the following oncology society meetings were also searched for relevant abstracts, again using the search terms “BMS-354825” OR “BMS354825”:

- American Society of Hematology (ASH) 2004
- American Society for Clinical Oncology (ASCO) 2004 and 2005
- American Association for Cancer Research (AACR) 2004
- European Society for Medical Oncology (ESMO) 2004
- European Hematology Association (EHA) 2004.

A total of 23 abstracts was identified, seven of which were disregarded on the basis of not concerning dasatinib (n=1) or not being relevant to the treatment of CML (n=6). Among the relevant abstracts, nine reported on the outcomes of preclinical studies, and seven on preliminary clinical data (Table 1).

**Table 1** | Evidence base included in the review (preclinical and phase I only)

Category	Number of records	
	Full papers	Abstracts
Initial search	6	23
records excluded	0	7
records included	6	16

## Disease overview

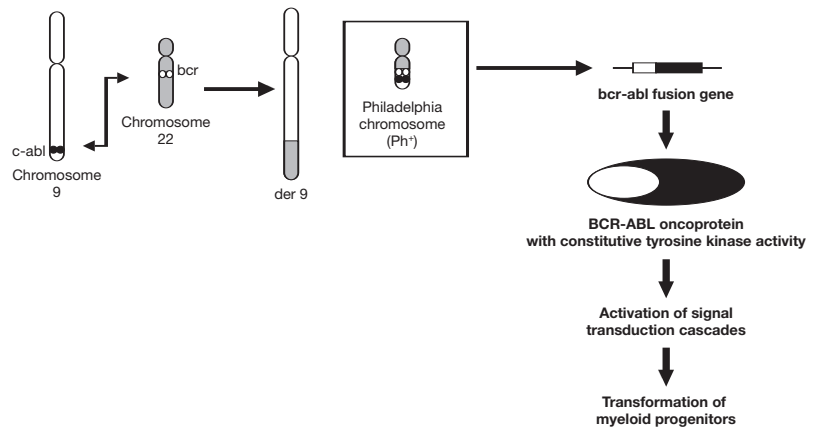

CML, also known as chronic myelogenous leukemia, is a clonal myeloproliferative disorder that originates from a single abnormal hematopoietic stem cell (Faderl et al. 1999; John et al. 2004; Stone 2004). Myeloid progenitors expand at various stages of maturation and are released prematurely from the bone marrow into the peripheral blood, subsequently infiltrating extramedullary sites, particularly the spleen. In the advanced stages of the disease (accelerated phase or blast crisis) the liver and lymph nodes may also become involved.

## Epidemiology

CML accounts for around 15% of all adult leukemias and is slightly more common in males than females (ratio 1.3 : 1). The incidence of CML is estimated at 1–2 new cases per 100 000 per annum (Maness & McSweeney 2004), and increases with advancing age (Fig. 1). The median age at CML diagnosis is 45–55 years, although 12–30% of patients present after the age of 60 years, and 10% present before their 20th birthday (Cortes et al. 1996, 1997; Faderl et al. 1999; Hill & Meehan 1999; Jemal et al. 2002; Besa 2004).

**Fig. 1** | Age-specific incidence rate of chronic myeloid leukemia (CML) (1995–1998) increases with age. National Cancer Institute Surveillance Epidemiology and End Results (SEER) data (Table XIII-6, chronic myeloid leukemia), which is publicly available at [http://seer.cancer.gov/csr/1973\\_1999/leukemia.pdf](http://seer.cancer.gov/csr/1973_1999/leukemia.pdf); graph adapted from the Leukemia and Lymphoma Society website: [http://www.leukemia-lymphoma.org/all\\_mat\\_detail.adp?item\\_id=2119&sort\\_order=48cat\\_id=1209](http://www.leukemia-lymphoma.org/all_mat_detail.adp?item_id=2119&sort_order=48cat_id=1209)

**Fig. 2** | The Philadelphia translocation: a balanced reciprocal translocation between chromosomes 9q and 22q, resulting in the creation of the bcr-abl fusion gene

### Molecular basis of CML

At the molecular level CML is caused by the constitutive expression of the bcr-abl oncogene which is created by a balanced reciprocal translocation between chromosomes 9q and 22q (Fig. 2) (Nowell & Hungerford 1960; Rowley 1973; Faderl et al. 1999). This translocation, known as the Philadelphia translocation, results in the joining of the 3' segment of the abl (Ableson leukemia virus) gene on 9q34 and the 5' segment of the bcr (breakpoint cluster region) gene on 22q11, to form the bcr-abl hybrid fusion gene carried on a shortened chromosome 22. This shortened chromosome 22, known as the Philadelphia chromosome (Ph<sup>+</sup>), is the hallmark of CML.

The BCR-ABL oncoprotein is a deregulated nonreceptor tyrosine kinase with increased activity compared with the 'wild-type' ABL kinase. Constitutive expression of BCR-ABL leads to malignant transformation by interfering with the signal transduction pathways involved in the control of apoptosis, cellular proliferation, and adherence of CML progenitors to bone marrow stromal elements (Goldman 1997; Faderl et al. 1999; John et al. 2004).

In 50–80% of CML cases, disease progression is associated with the acquisition of additional cytogenetic and molecular genetic changes, which often precede hematologic and clinical manifestations. Minor cytogenetic changes include monosomies of chromosomes 7 and 17 (one chromosome missing), trisomies of chromosomes 17 and 21 (an extra chromosome), and a translocation between chromosomes 3 and 12 [t(3;12)(q26,q22)] (Mitelman 1993). Major cytogenetic changes include trisomy 8, isochromosome 17q, trisomy 19, and an additional Philadelphia chromosome (disomy Ph<sup>+</sup>) (Kantarjian et al. 1987; Derderian et al. 1993; Mitelman 1993). The most frequent molecular abnormalities are alterations to the tumor suppressor, p53 (Ahuja et al. 1989).

### Signs and symptoms

The onset of CML is associated with signs and symptoms that usually develop gradually. Most patients experience fatigue and reduced exercise tolerance due to anemia. Discomfort on the left side of the abdomen is also a frequent complaint as a result of splenomegaly. In addition, patients with CML often develop a hypermetabolic state, which is associated with fever, excessive sweating, and weight loss (Faderl et al. 1999; Hill & Meehan 1999; Besa 2004).

### Disease staging

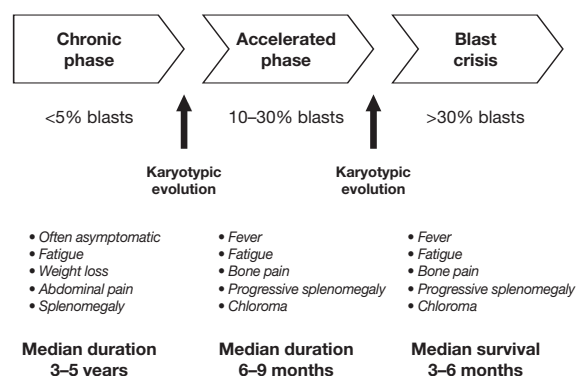

CML follows a triphasic clinical course (Fig. 3). Initially there is the chronic phase, in which the disease is often indolent, followed by the accelerated phase, and subsequent progression to the terminal phase, known as blast crisis (Faderl et al. 1999; Hill & Meehan 1999; Maness & McSweeney 2004).

#### Chronic phase

The chronic phase is characterized by <5% blasts (immature myeloid leukemic cells) in the blood and bone marrow; no malignant cells outside of the blood, bone marrow, or spleen; and absent/mild symptoms of CML. Most patients (~80%) are in the chronic phase at diagnosis. The median duration of the chronic phase is 3–5 years, before progression to the accelerated phase.

#### Accelerated phase

The accelerated phase is defined by the presence of one or more of the following: persistent presence of 10–30% blasts in the blood and bone marrow; white blood cell count >50 000/ $\mu$ L with an increase or decrease in platelets and low red blood cell count despite treatment; progressive splenomegaly; involvement of

**Fig. 3** | Chronic myeloid leukemia: triphasic clinical course

organs other than the bone marrow or spleen; acquired cytogenetic abnormalities additional to the Philadelphia chromosome; and persistent, unexplained fever or bone pain. The accelerated phase of CML is generally short-lived, with progression to blast crisis within a median of 6–9 months.

### Blast crisis

The final stage of CML, blast crisis, is defined by the presence of >30% blasts in the blood and bone marrow. These immature leukemic blasts may form tumor masses in the bone or lymph nodes. At this stage, the disease is considered to have progressed to an aggressive, acute form of leukemia that is rapidly fatal, with a median survival of 3–6 months. In one-third of cases, the blasts develop a lymphoid morphology and begin to express lymphoid markers, whereas in the remaining two-thirds the blasts have a phenotype similar to that of acute myeloblastic leukemia (Griffin et al. 1983). It is important to distinguish between these two groups of patients because those whose leukemia is in lymphoid blast crisis (Ph+ ALL) can respond to treatment with regimens that are active against acute lymphoid leukemia (Derderian et al. 1993), whereas patients with myeloid morphology do not.

### Diagnosis

Approximately 50% of patients with CML are asymptomatic at diagnosis; their disease being discovered after routine blood films show leukocytosis. Initial evaluations typically involve a physical examination and morphologic review and immunotyping of the blood, bone marrow, and, where appropriate, a lymph node or spleen biopsy. However, a confirmed diagnosis of CML depends on demonstrating the presence of the Ph+ chromosome cytogenetically in the bone marrow (detected in 95% of patients), or detecting the presence of the bcr-abl oncogene by polymerase chain reaction (PCR), fluorescent *in situ* hybridization (FISH), or Southern analysis; detecting the BCR-ABL transcript by RT-PCR or Northern analysis; or demonstrating the presence of the BCR-ABL oncoprotein by Western analysis (Faderl et al. 1999; Hill & Meehan 1999; Vardiman et al. 2001).

### Evaluation of response

Response to therapy for CML can be evaluated on three levels. In increasing order of remission depth these are hematologic responses, cytogenetic responses, and molecular responses.

A complete hematologic response refers to normalization of blood counts lasting for at least 4 weeks. However, patients who achieve complete hematologic responses may still have detectable levels of Ph+ cells. A complete cytogenetic response refers to the absence of Ph+ cells on cytogenetic analysis. For patients who achieve complete cytogenetic responses, a more sensitive measurement of residual disease may be conducted using BCR-ABL transcripts, detected by reverse transcriptase PCR (RT-PCR), as a marker for residual disease. Elimination of residual disease to levels below the limit of detection by RT-PCR is known as a complete molecular remission. Incomplete cytogenetic responses are referred to as major or minor responses according to the percentages of Ph+ cells detected.

<sup>a</sup>Phase I trial initiated

**Fig. 4** | Advances in the treatment of chronic myeloid leukemia: an historical perspective. allo-SCT, allogeneic stem cell transplant; BU, busulfan; HU, hydroxyurea; IFN- $\alpha$ , interferon- $\alpha$ ; MUD, matched unrelated donor

### Goals of therapy

The goal of therapy usually depends upon disease phase. For patients with chronic phase CML the principal goal of therapy has been to attain a complete cytogenetic response, as this has consistently been correlated with prolonged survival (Kantarjian et al. 1995, 2004; Clift & Storb 1996; Guilhot et al. 1997; ICSGCML 1998; Clift et al. 1999; Stone 2004). However, molecular responses are likely to become the new goal of therapy for these patients, with the aim of further improving response duration and overall survival. Other important objectives of therapy for patients in the chronic phase include normalizing blood counts (complete hematologic responses), controlling the signs and symptoms of CML, and delaying disease progression to the accelerated phase or blast crisis.

In contrast, for patients in the accelerated phase or blast crisis, the primary goal of therapy is often to reestablish the chronic phase. Regardless of therapy the prognosis for patients with accelerated or blast phase CML is currently poor (Shah et al. 2004a; Travis 2004).

### Current therapy options

Considerable advances have been made in the treatment of CML since the first patients were treated with Fowler's solution in the 1860s (Fig. 4).

#### Chemotherapy

Busulfan, an alkylating agent introduced in the 1950s, reduces white blood cell counts and disease-related signs and symptoms, but does not produce a complete cytogenetic response, or significantly delay disease progression. In addition, busulfan is poorly tolerated and is associated with serious adverse events, such as myelosuppression and pulmonary/hepatic/cardiac fibrosis (Hehlmann et al. 1993).

Treatment with hydroxyurea, a ribonucleotide reductase inhibitor, can achieve hematologic remissions and reduce splenomegaly, and offers a survival advantage over busulfan. Hydroxyurea is also better tolerated than busulfan, particularly with regard to bone marrow recovery. However, like busulfan, hydroxyurea produces neither a complete cytogenetic remission, nor a significant delay in disease progression to the accelerated phase or blast crisis (Hehlmann et al. 1993).

The investigational drug, homoharringtonine, a plant alkaloid protein synthesis inhibitor, is also active in CML as monotherapy and in combination with cytarabine (Kantarjian et al. 2000, 2001). In patients with late chronic phase CML (diagnosed for >12 months) treatment with homoharringtonine produced complete hematologic and cytogenetic responses in 72 and 31%, respectively (O'Brien et al. 1995). However, high doses and short infusion schedules of homoharringtonine are associated with serious cardiovascular complications, including hypotension and cardiac arrhythmias (Kantarjian et al. 2000, 2001). Consequently homoharringtonine has not received approval for the treatment of CML.

### Allogeneic stem cell transplantation

Allogeneic hematopoietic stem cell transplantation (allo-SCT) is currently the only treatment with long-term data demonstrating curative potential in CML (Stone 2004). This is due to the graft-versus-leukemia (GVL) effect, an immunotherapeutic phenomenon in which allogeneic T and NK cells recognize and destroy tumor cells (Bleakley & Riddell 2004).

Up to 70% of patients with early chronic phase CML are cured following allo-SCT (Stone 2004). However, the probability of long-term survival is substantially reduced in patients who are transplanted in the accelerated or blast phases of the disease (Cliff & Storb 1996; Horowitz et al. 1996), and progressively worsens with advancing age (Cliff & Storb 1996; Gratwohl & Hermans 1996; Gratwohl et al. 1998). Furthermore, allo-SCT procedures are associated with significant morbidity [graft-versus-host disease (GVHD) and infections], and high rates of treatment-related mortality (20–40%) (Silver et al. 1999). An HLA-matched, related donor is optimal, but is available for <30% of patients (Cliff & Storb 1996; Horowitz et al. 1996). In the absence of an HLA-matched, related donor, an HLA-matched, unrelated donor transplant may be considered, but is usually associated with increased morbidity (GVHD and infections, including cytomegalovirus reactivation) and an increased risk of treatment-related mortality, compared with an HLA-matched, related donor transplant (Hansen et al. 1998; Weisdorf et al. 2002).

Considering the current evidence, the best candidates for allo-SCT would therefore appear to be young patients with recently diagnosed, early-stage disease for whom matched, related donors are available. Consequently, <40% of patients with CML are eligible for allo-SCT procedures, despite its curative potential. However, recently developed reduced-intensity conditioning regimens for

allo-SCT have been associated with reduced morbidity and mortality risks, and are likely to extend this potentially curative procedure to patients previously considered ineligible because of age and/or advanced disease (i.e. CML in the accelerated phase or blast crisis) (Or et al. 2003).

### Interferon

The mechanism of action of interferon- $\alpha$  (IFN- $\alpha$ ) is poorly understood. For patients with chronic phase CML, IFN- $\alpha$  produces complete cytogenetic responses in 8–38% of patients (ICSGCML 1998), and significantly prolongs survival compared with hydroxyurea or busulfan (Hehlmann et al. 1994; ICSGCM 1994). Furthermore, patients who achieve major cytogenetic responses following treatment with IFN- $\alpha$  survive longer, compared with those who fail to achieve a major cytogenetic response (Kantarjian et al. 1995). In common with other treatments for CML, IFN- $\alpha$  is most effective in the chronic phase of the disease (Kantarjian et al. 1998).

In a randomized study comparing the safety and efficacy of IFN- $\alpha$  + cytarabine vs IFN- $\alpha$  monotherapy in patients with chronic phase CML, the addition of cytarabine was associated with significantly higher complete hematologic response rates (66 vs 55%), major cytogenetic response rates (41 vs 24%), and significantly longer survival (3-year survival rates: 85.7 vs 79.1%) (Guilhot et al. 1997).

In a long-term follow-up of 512 patients with CML treated with IFN- $\alpha$  + cytarabine between 1981 and 1995, 27% achieved complete cytogenetic remissions, and among those patients achieving complete cytogenetic remissions, 78% achieved 10-year survival. This confirms the importance of complete cytogenetic remission as a therapeutic goal in CML (Kantarjian et al. 1995).

The major drawback of IFN-based therapy is its poor tolerability profile: 10–25% of patients discontinue treatment due to flu-like syndrome, anorexia, and depression (ICSGCML 1994; Guilhot et al. 1997). However, despite its poor tolerability profile, IFN- $\alpha$  + cytarabine was the standard of care for many years before the introduction of imatinib mesylate, and is still used today.

### Imatinib mesylate

The BCR-ABL oncoprotein is the most directly relevant therapeutic target in CML. Imatinib mesylate, a small molecule developed specifically to inhibit BCR-ABL kinase activity, has revolutionized the treatment of CML, and is currently the gold

**Table 2** | Imatinib: phase II responses in treatment of chronic myeloid leukemia

Response	Phase of disease				
	Chronic (Kantarjian et al. 2002)	Accelerated (Talpaz et al. 2002)		Blast crisis (Sawyers et al. 2002)	
		400 mg/day	400 mg/day	600 mg/day	400 mg/day
Complete hematologic	95%	27%	37%	0%	9%
Complete cytogenetic	41%	11%	19%	3%	8%
Major cytogenetic	60%	16%	28%	6%	18%
Minor cytogenetic	5%	8%	6%	3%	2%

**Table 3** | IRIS trial: phase III responses

Category	Imatinib	IFN-alfa/ cytarabine	P
Complete hematologic response	95.5%	55.5%	<0.001
Complete cytogenetic response	73.8%	8.5%	<0.001
Molecular responses (3-log reduction in BCR-ABL transcripts at 12 months)	39%	2%	<0.001
Survival	6.2-year survival advantage with imatinib over IFN-alfa/cytarabine		
IFN-alfa, interferon-alfa.			

standard treatment for all phases of CML (Druker et al. 1996, 2001a,b; Peggs & Mackinnon 2003). Phase II studies confirmed the ability of imatinib to produce both complete hematologic and cytogenetic remissions in patients in all phases of CML (Kantarjian et al. 2002; Sawyers et al. 2002; Talpaz et al. 2002). As expected, outcomes were best among patients with chronic phase CML, compared with patients with more advanced disease (see Table 2). In addition, a randomized phase III trial (IRIS) comparing the safety and efficacy of imatinib vs IFN-alfa + cytarabine in 1106 patients with newly diagnosed CML demonstrated that not only was imatinib much better tolerated than IFN-alfa + cytarabine, it was also significantly more effective than IFN-alfa + cytarabine with regard to complete hematologic response rates (O'Brien et al. 2003), complete cytogenetic response rates (O'Brien et al. 2003), molecular responses (Hughes et al. 2003), and overall survival (Anstrom et al. 2004) (summarized in Table 3). Furthermore, baseline quality of life was maintained among patients treated with imatinib, whilst quality of life markedly deteriorated among patients treated with IFN-alfa + cytarabine ( $P=0.001$ , Hahn et al. 2003).

The efficacy of high-dose imatinib therapy in chronic phase CML has recently been investigated. The outcomes of these studies are summarized in Table 4. A small single-arm study conducted in patients with chronic phase CML who had failed treatment with IFN-alfa suggested that high-dose imatinib (400 mg twice a day) improved cytogenetic and molecular response rates without increasing toxicity, compared with responses typically achieved with standard-dose imatinib (400 mg once a day) (Cortes et al.

2003). These findings were subsequently confirmed in an independent study conducted in patients with newly diagnosed CML (Kantarjian et al. 2004). Dose escalation of imatinib to 600 mg once a day or 400 mg twice a day also appears to be effective in overcoming disease relapse/refractoriness in patients who have failed treatment with standard-dose imatinib (Kantarjian et al. 2003).

Imatinib has generally been well tolerated, even in high-dose trials. The majority of adverse events were of mild-to-moderate severity, and the most frequently reported adverse events were edema, nausea, diarrhea, muscle cramps, and rash. However, myelosuppression was more frequent in patients with accelerated phase or blast crisis CML and in patients treated with high-dose imatinib regimens.

In summary, extensive experience with imatinib in clinical trials has shown this agent to be highly effective and well tolerated in the treatment of CML. In common with other treatments for CML, best responses are achieved in patients with chronic phase disease; up to 90% of patients achieve complete cytogenetic remissions following treatment with high-dose imatinib, and up to 41% achieve molecular remissions in which BCR-ABL transcripts are undetectable by RT-PCR.

#### Treatment guidelines

Although guidelines for the treatment of CML are available (ASH 1999), these are out of date as they do not take into account the advances in treatment achieved with imatinib. Since the establishment of imatinib as first-line treatment for CML, one of the key dilemmas facing healthcare providers is how best to incorporate it into the treatment of patients who are candidates for potentially curative (but toxic) allo-SCT procedures (Deininger et al. 2003; Peggs & Mackinnon 2003). Consequently, ASH is planning to update its existing guidelines in the near future (ASH online, accessed February 14, 2005).

#### Cost of care

Although several studies have investigated the cost-effectiveness of individual treatment strategies in specific patient subgroups (Kattan et al. 1996; Lee et al. 1998; Beck et al. 2001; Dalziel et al. 2004; Reed et al. 2004; Warren et al. 2004), few data are available regarding the overall economic and societal costs of CML.

**Table 4** | High-dose imatinib in patients with chronic myeloid leukemia in chronic phase

Patient group	Responses		
	Hematologic	Cytogenetic	Molecular
Failed treatment with interferon-alfa	100% (complete)	89% (complete)	56% (BCR-ABL transcripts undetectable in 41%)
Newly diagnosed	Not reported	90% (complete)	63% (BCR-ABL transcripts undetectable in 28%)
Hematologic resistance/relapse with standard dose imatinib	45% (complete) 20% (partial)	10% (partial)	Not reported
Cytogenetic resistance/relapse with standard dose imatinib		56% (complete or partial)	Not reported

## Unmet needs

Although most CML patients respond well to initial treatment with imatinib, resistance is a major problem. Indeed, a minority of previously untreated patients are resistant to imatinib from the outset (innate resistance), and the majority of those who initially respond to imatinib subsequently develop resistance (acquired resistance).

Treatment options for patients with imatinib-resistant CML are limited to allo-SCT, assuming the patient is eligible and a suitable donor is available, or investigational therapies, such as farnesyltransferase inhibitors (Hoover et al. 2002) or arsenic trioxide (La Rosee et al. 2002). Furthermore, the onset of imatinib resistance appears to correlate with disease progression and worsening prognosis (Shah et al. 2002). Therefore there is a need for novel agents to override imatinib resistance in CML.

An agent that produces complete cytogenetic and molecular responses, delays disease progression, and significantly improves survival expectation in imatinib-resistant CML patients would represent a major advance in the treatment of CML.

To develop new strategies to overcome imatinib resistance it is necessary to understand the underlying resistance mechanisms. Clinical resistance is primarily mediated by the acquisition of mutations within the BCR-ABL oncoprotein that prevent imatinib binding, and to a lesser extent by bcr-abl gene amplification. Other mechanisms of resistance that have been suggested include elevated levels of multidrug resistance protein, and overexpression of SRC kinases (Mahon et al. 2000; Nardi et al. 2004; Stone 2004).

The activation loop of ABL kinase oscillates between open (active) and closed (inactive) conformations. Imatinib can only bind when the activation loop is in the closed (inactive) conformation, locking the kinase in the inactive state (Schindler et al. 2000). At least 17 different amino acid substitutions within BCR-ABL have been identified that cause imatinib resistance by preventing imatinib binding (Hochhaus et al. 2002; Roche-Lestienne et al. 2002; Shah et al. 2002; von Bubnoff et al. 2002; Al-Ali et al. 2004). Some of these mutations directly affect the imatinib binding site. However, the majority of imatinib-resistance mutations occur in the activation loop, locking it into the open (active) conformation, which precludes imatinib binding.

Structural studies have demonstrated that pyridol[2,3-*d*]pyrimidine dual SRC-ABL kinase inhibitors bind to BCR-ABL, inhibiting its kinase activity, regardless of whether the activation loop is in the open (active) or closed (inactive) conformation (Nagar et al. 2002). In principle, the dual SRC-ABL inhibitors, which have less stringent binding requirements than imatinib, could potentially override imatinib resistance due to their ability to bind to and inhibit ABL kinase when the activation loop is in the open (active) conformation.

The potential utility of dual SRC-ABL inhibitors to override imatinib resistance in CML is further supported by recent data indicating that imatinib resistance is associated with upregulated expression of the SRC kinase, Lyn (Donato et al. 2004; Wu et al. 2004).

## Drug review

Dasatinib is a dual function SRC-ABL kinase inhibitor currently being developed for the treatment of patients with imatinib-

resistant CML. The discovery of dasatinib is discussed in a recent review (Lombardo et al. 2004).

### Preclinical evidence

#### *X-ray crystallography*

X-ray crystallography has confirmed that, like imatinib, dasatinib binds to the adenosine triphosphate binding site of ABL kinase with the central cores of the two drugs occupying overlapping regions, but extending in opposite directions. This study confirmed the ability of dasatinib to bind to ABL kinase when the activation loop is in the open (active) conformation, thus confirming the theoretical potential for dasatinib to override imatinib resistance. Furthermore, there were no apparent steric clashes to preclude dasatinib from binding when the activation loop is in the closed (inactive) conformation (Tokarski et al. 2004). This apparent ability of dasatinib to bind to ABL kinase in multiple conformational states indicates that it may have the potential for greater potency compared with imatinib.

#### *Evidence for in vitro activity against imatinib-resistant BCR-ABL isoforms*

*In vitro* cell-based assays have demonstrated that dasatinib is more potent ( $\times 2$ -log) than imatinib in inhibiting unmutated BCR-ABL activity (Shah et al. 2004a). This increased potency may be due to the apparent ability of dasatinib to bind to ABL kinase in multiple conformational states (Tokarski et al. 2004).

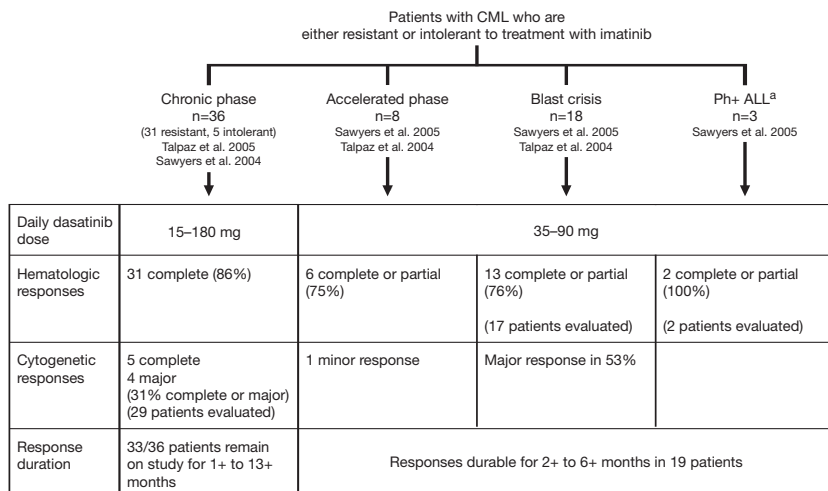

Dasatinib has also shown *in vitro* activity against 14 of 15 imatinib-resistant cell lines expressing mutant BCR-ABL isoforms, demonstrated by inhibition of kinase activity, and inhibition of cell growth (Shah et al. 2004a). The one imatinib-resistant cell line that was also resistant to dasatinib carried the T315I mutation, suggesting that this mutation confers cross resistance to both imatinib and dasatinib. The sensitivity of the different imatinib-resistance mutations to treatment with dasatinib was varied. This suggests that, in the future, individual patient's BCR-ABL mutation status may guide decision making regarding the minimum serum concentrations of dasatinib required for therapeutic benefit.

In addition to the apparent ability of dasatinib to override imatinib resistance caused by mutations in BCR-ABL, recent *in vitro* data suggest that, like imatinib, dasatinib is selective for leukemic vs normal hematopoietic stem cells. Dasatinib (5 nM) did not inhibit growth of bone marrow progenitors isolated from healthy volunteers, but did result in 60–80% growth inhibition in bone marrow progenitors isolated from CML patients with unmutated BCR-ABL or M351T imatinib-resistant BCR-ABL (Shah et al. 2004a).

A battery of pharmacogenomic biomarkers (other than BCR-ABL mutations) have also been identified, which predict sensitivity to dasatinib in tumor cell lines (Clark et al. 2005).

#### *Evidence of antileukemic activity in mouse models of imatinib-sensitive and imatinib-resistant CML*

Models of BCR-ABL-dependent disease have been produced by injecting mice with cell lines that express unmutated BCR-ABL, or imatinib-resistant BCR-ABL isoforms (Shah et al. 2004a,b). Following administration of dasatinib (10 or 15 mg/kg),

**Fig. 5 |** Phase I responses following treatment with dasatinib in patients with Ph+, imatinib-resistant/intolerant chronic myeloid leukemia (CML)

<sup>a</sup>CML in blast crisis where blasts have developed lymphoid morphology.

phosphorylation of CRKL (a BCR-ABL substrate) was inhibited for up to 7 h, returning to baseline after 12 h. Based on these preliminary data, a dose of 10 mg/kg was chosen for evaluation of dasatinib efficacy.

Three days after injecting the cell lines, mice were treated with vehicle or dasatinib for 2 weeks. All vehicle-treated mice developed progressive disease, with massive hepatic and splenic infiltration, which resulted in death in around 15 days. Conversely, dasatinib-treated mice with unmutated BCR-ABL tumors or M351T (imatinib-resistant) tumors appeared to be healthy (no weight loss, lethargy, or ruffled fur), and showed a >1-log decrease in BCR-ABL kinase activity (measured by bioluminescence assay), normal spleen weight, and significantly longer survival compared with vehicle-treated animals. Consistent with *in vitro* studies, mice with T315I BCR-ABL tumors did not respond to treatment with dasatinib (no significant reduction in kinase activity by bioluminescence assay) and showed no significant improvement in survival compared with vehicle-treated animals.

Treatment with dasatinib at doses as low as 5 mg/kg per day has been shown to be curative in other murine xenograft models of imatinib-resistant CML (Lee et al. 2004).

*Evidence for antileukemic activity in a mouse model of intracranial CML*

Growing evidence suggests that imatinib is a poor penetrator of the blood–brain barrier, resulting in subtherapeutic levels of the drug in the central nervous system. Several clinical cases have been reported in which central nervous system relapse has occurred despite complete hematologic responses in the blood and bone marrow (Leis et al. 2004). Furthermore, in at least one animal model of CML, imatinib has shown limited ability to cross the blood–brain barrier, allowing the central nervous system to act as a sanctuary for leukemic cells (Wild et al. 2004).

It has been suggested that the limited ability of imatinib to cross the blood–brain barrier may be due to the fact that it is a substrate for

P-glycoprotein. In contrast, dasatinib is not a P-glycoprotein substrate, and is therefore more likely to achieve therapeutic levels in the central nervous system. To test this hypothesis a mouse model of intracranial CML was created by transplanting K562 CML tumors intracranially. Mice were treated with dasatinib twice daily for up to 40 days. Tumor regression was achieved at a dasatinib dose of 15 mg/kg, with complete stasis of intracranial tumor growth during therapy. In addition, survival was increased by 450 and 268% at dose levels of 15 and 5 mg/kg, respectively. These preliminary data indicate that dasatinib may potentially offer advantages over imatinib in the management of intracranial CML (Wild et al. 2004).

*Pharmacokinetic profile in mice*

In a model of BCR-ABL-dependent disease, oral dasatinib was curative over a range of doses (1.25–50 mg/kg). At the minimum effective dose of 1.25 mg/kg, maximum inhibition of BCR-ABL activity was observed 3 h after dosing, with complete recovery of BCR-ABL activity in 7–17 h. This model predicted that a minimum plasma concentration of 20 nM is required to effectively inhibit BCR-ABL activity. In addition, while a 1.25 mg/kg per day dose was curative with twice-daily dosing, a higher 5 mg/kg per day dose was required for equivalent efficacy with once-daily dosing, suggesting that twice-daily dosing regimens may be more effective than once daily (Luo et al. 2004).

**Clinical evidence**

Patients with CML who are resistant or intolerant to previous treatment with imatinib were enrolled onto a phase I dose escalation study (Fig. 5). This study included 36 patients with chronic phase CML, eight patients with accelerated phase CML, 18 patients in blast crisis, and three patients with Ph+ ALL. Patients with chronic phase CML were treated with dasatinib at doses of 15–180 mg/day (as a single dose or split into two equal doses) for 5–7 days/week, whilst patients in the accelerated phase or blast crisis were treated with dasatinib at doses of 35–90 mg/day twice daily. Responses according to phase of disease are summarized below.

*Phase I responses: patients with chronic phase CML*

To date 36 patients with chronic phase CML enrolled onto this phase I study (imatinib resistant n=31, imatinib intolerant n=5, BCR-ABL mutations associated with imatinib resistance n=27) have been followed for >4 weeks and were evaluable for response (Sawyers et al. 2004; Talpaz et al. 2005).

Thirty-one patients (86%) achieved a complete hematologic response. Only two patients experienced disease progression: one of whom carried the imatinib resistance mutation, T315I, which was also associated with resistance to dasatinib in preclinical studies.

Twenty-nine patients were evaluated cytogenetically: 13 demonstrated cytogenetic improvement, including five complete and four major cytogenetic responses. Hematologic and cytogenetic responses were achieved in patients with or without BCR-ABL mutations (Sawyers et al. 2004; Talpaz et al. 2005; Shah et al. 2005). Furthermore, these responses were durable with 33 of 36 patients remaining on study for 1+ to 13+ months (Talpaz et al. 2005).

BCR-ABL transcripts were monitored by quantitative RT-PCR in a subset of 13 patients treated with dasatinib (Shah et al. 2004c). Four patients (three imatinib resistant, two of whom carried the known imatinib-resistance mutation, M351T) achieved a major cytogenetic response, which corresponded with 1- or 2-log reductions in BCR-ABL transcript levels, and an overall 32% median reduction in BCR-ABL transcripts after 4 weeks of treatment. In contrast, none of the nine patients who failed to achieve a major cytogenetic response achieved a 1-log reduction in BCR-ABL transcript levels.

These preliminary data therefore indicate that the achievement of a major cytogenetic response is associated with 1- or 2-log reduction in BCR-ABL transcript expression. In addition, quantitative RT-PCR appears to offer a rapid and reliable method of monitoring disease burden and response to therapy in this setting (Shah et al. 2004c). It is worthy of note that similar reductions in BCR-ABL transcript levels have previously correlated with cytogenetic responses achieved with imatinib (Shah et al. 2004c).

*Responses in patients with accelerated phase CML, blast crisis, or Ph+ ALL*

To date, 29 patients with accelerated phase CML (n=8), blast crisis (n=18), or Ph+ ALL (n=3) who entered this phase I trial have received treatment with dasatinib (Talpaz et al. 2004; Sawyers et al. 2005). Of 28 patients for whom BCR-ABL mutation status was known, 16 had mutations known to confer imatinib resistance. Hematologic response rates (complete and partial) were as follows: 75% (six of eight) in patients with accelerated phase CML, 76% (13 of 17) in patients in blast crisis, and 100% (two of two) in patients whose disease had transformed to Ph+ ALL. These responses were durable for 2+ to 6+ months in 19 patients (Sawyers et al. 2005).

Among patients in blast crisis, 53% achieved a major cytogenetic response. Of note, the T315I mutation, which conferred cross resistance to both imatinib and dasatinib in preclinical models, was identified in four of six patients who were resistant to dasatinib therapy.

*Safety and tolerability*

Dasatinib treatment was generally well tolerated regardless of disease phase. In patients with chronic phase CML, three of 36 developed grade 4 thrombocytopenia and two of 36 developed grade 4 neutropenia, all of which were reversible and easily managed with dose modification. One patient developed a duodenal ulcer, and mild QTc prolongation was noted (Talpaz et al. 2005). In patients with advanced disease, eight of 29 developed grade 4 thrombocytopenia, one patient developed grade 3/4 fluid retention, and two patients developed tumor lysis syndrome (Sawyers et al. 2005).

Src inhibitors are known to be important modulators of T-cell activation. It is therefore noteworthy that a recent report indicated that dasatinib induces complete hematologic remission without affecting the ability of CD8<sup>+</sup> and CD4<sup>+</sup> T cells to produce Th1 and Th2 cytokines when stimulated (Gao et al. 2005).

Overall, these preliminary phase I data indicate that dasatinib is frequently able to override imatinib resistance in patients with chronic phase disease and those with more advanced disease (accelerated phase or blast crisis). The drug also appears to be well tolerated, regardless of the disease phase. The maximum tolerated dose has yet to be established and dose escalation continues to establish the dose range that yields optimal results.

Based on these encouraging data, phase II studies of dasatinib in the treatment of patients with imatinib-resistant CML are planned.

**Resource utilization**

Dasatinib is still in the preliminary stages of clinical development, and its future use in the treatment of CML will depend upon the outcomes of phase II and III trials. However, the available preliminary data suggest that it may potentially provide a much needed therapeutic option for patients with imatinib-resistant CML. The future use of dasatinib in the treatment of CML is likely to depend on its safety profile. In particular, Src kinase inhibition is associated with immunosuppression, which raises the possibility that treatment with dasatinib might be associated with more adverse events than imatinib (Doggrell 2005). Long-term follow-up data will therefore be required to fully assess the safety profile of dasatinib.

In a screen for BCR-ABL mutations conferring resistance to imatinib and dasatinib, the mutation profiles conferring resistance to the two drugs were different and 30–50-fold fewer mutant clones were resistant to both imatinib and dasatinib, compared with each drug individually (Burgess et al. 2004). This suggests that dasatinib in combination with imatinib could potentially be useful in the first-line management of CML, particularly with regard to delaying the development of drug resistance.

In addition, given the apparent potency of dasatinib, its use in combination with other agents known to be active in CML could potentially be an effective strategy for purging residual disease and achieving molecular remissions.

**Drug profile**

Although imatinib has proven to be extremely effective in first-line treatment of CML, producing hematologic, cytogenetic, and molecular remissions, resistance to the drug frequently develops.

Imatinib resistance is problematic for two reasons: alternative therapeutic options are extremely limited, and the onset of imatinib resistance is usually associated with disease progression and worsening prognosis. There is therefore a need for new treatment strategies to be developed to override imatinib resistance in CML.

Dasatinib is an orally active SRC-ABL inhibitor that is currently in development for the treatment of imatinib-resistant CML. This compound has shown potent antileukemic activity in cell lines expressing imatinib-resistant BCR-ABL isoforms, and striking remissions and significant prolongation of survival in a series of xenograft mouse models of imatinib-sensitive and imatinib-resistant CML. Furthermore, dasatinib has shown promising *in vitro* activity against malignant bone marrow cells isolated from patients with imatinib-resistant CML. The apparent ability of dasatinib to cross the blood-brain barrier in mice suggests that it might also prove useful in the treatment of patients with intracranial CML.

Preliminary evidence from the initial phase I dose escalation study is encouraging, indicating that dasatinib can induce hematologic and cytogenetic responses in patients with imatinib-resistant CML in all phases of the disease. However, although dasatinib appears to be able to override the majority of BCR-ABL mutations that cause imatinib resistance, it does not inhibit at least one widespread imatinib-resistant BCR-ABL isoform (T315I) (Shah et al. 2005). Dasatinib appears to be generally well tolerated, regardless of disease phase, and long-term tolerability data are eagerly awaited.

Although dasatinib is still in the initial stages of clinical development, early evidence suggests that its potential impact on the treatment of CML could be substantial. Not only could dasatinib provide a much needed treatment option for patients with imatinib-resistant CML, but also, combined with imatinib, it might prove to be useful in delaying the onset of resistance seen with imatinib monotherapy. Furthermore, dasatinib, in combination with other agents known to be active in CML, may also prove useful for purging the residual leukemic cells that persist even in patients whose disease is controlled by imatinib.
