Abstract: Necrotizing autoimmune myopathy is characterized by predominant muscle fiber necrosis and regeneration with little or no inflammation. We describe a 58-year-old woman with previous breast cancer and statin use who complained of rapidly progressive weakness of lower limbs without pain, making walking, running and climbing stairs difficult. The creatine kinase level was 2,843 U/L, and muscle biopsy showed a dystrophic pattern. The genetic test for muscular dystrophies was negative and for anti-3-hydroxy-3-methylglutaryl coenzyme A reductase was positive. Intravenous immunoglobulin was administered, which showed mild improvement. Unfortunately, she took a step and collapsed to the floor, which led to the fracture of right femur delaying her improvement. The diagnosis of necrotizing autoimmune myopathy is sometimes delayed due to the atypical pathologic findings on muscle biopsy. As the disease is a severe condition, prompt recognition can lead to a successful outcome. We advise to consider this entity as a differential diagnosis among muscular dystrophies.

Keywords: necrotizing autoimmune myopathy, HMGCR antibody, muscular dystrophy, cancer, statin

Introduction

Since 2003, an international workshop exposed different points of view to improve the classification criteria of different inflammatory myopathies designed by Anthony Amato, allowing us an accurate diagnosis.

Among the different inflammatory myopathies, a special histologic pattern defined a new subgroup called immune-mediated necrotizing myopathy or necrotizing autoimmune myopathy (NAM), which is characterized by predominant muscle fiber necrosis and regeneration with little or no inflammation.^{1,2}

It has been known that patients with NAM have specific autoantibodies that are associated with specific clinical phenotypes. Thus, they can be grouped into myositis-specific autoantibodies, myositis-associated autoantibodies, signal recognition particle (SRP) and, more recently, antibodies to 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMGCR). Although there are other risk factors recognized for NAM as cancer and, rarely, the HIV infection, prompt recognition of anti-SRP and anti-HMGCR myopathy is very important as the early immunosuppressive therapy is the treatment of choice often followed by improvement in strength.^{3,4}

Case presentation

A 58-year-old woman with no previous medical history of neuromuscular disorder was referred to our outpatient clinic in August 2014, complaining of weakness of the right foot for 1 year that progressed after 3 months with weakness of the left foot without pain. The worsening was progressive, making walking, running and climbing stairs difficult within 1 year.

She had unrelated parents and a familial history that revealed no abnormalities.

A breast neoplasia (invasive ductal carcinoma) was diagnosed in January 2007. She underwent a mastectomy with lymphadenectomy followed by chemotherapy. Currently, the breast neoplasia has been controlled with no complaints.

Between 2012 and 2014, she had taken 20 mg/day of simvastatin without side effects. She discontinued the medication 3 months after the beginning of symptoms.

In July 2017, she was diagnosed with colon adenoma without surgery.

Her first assessment revealed muscle weakness, which was proximal–distal in the lower limbs, revealing a distal atrophy. The muscle strength was 4- out of 5 (Medical

Researcher Council) in the quadriceps and hamstring muscles and 4 in the gastrocnemius and soleus muscles. The tibialis anterior muscle strength was 5. The upper limbs showed a normal strength of proximal and distal muscles. No facial weakness was detected. Her deep tendon reflexes were preserved. No sensitive abnormalities were present. No retractions were found. No cardiac involvement or respiratory dysfunction was observed.

Serologic tests for autoimmune disorders were all normal. Creatine kinase (CK) was 2,843 U/L (26–140) and aldolase was equivalent to 25.9 U/L (<7.6). Other laboratory findings were within normal limits. The cerebrospinal fluid showed no neoplastic cells.

Conduction studies were normal and needle electromyography showed a myogenic pattern with positive waves.

Magnetic resonance imaging of the lower limbs revealed diffuse edema of the right semimembranosus and left semimembranosus and femoral biceps. There was discreet fatty infiltration of the soleus muscle and the medial and lateral heads of both gastrocnemii (Figure 1).

A muscle biopsy of the gastrocnemius was performed, which revealed myopathic changes, including marked variation

Figure 1 Axial muscle MRI of thighs and legs and muscle biopsy findings (gastrocnemius).

Notes: (A–H) MRI of the thighs: axial T1-weighted images (A and B) show mild fatty degeneration of right and left semimembranosus (arrow). Axial fat-suppressed T2-weighted images (C and D) reveal edema of the right semimembranosus and very mild edema of left semimembranosus (arrow) and long head of biceps femoris (arrow head). MRI of the legs: axial T1-weighted images (E and F) show fatty degeneration of medial head of gastrocnemius (arrow) and soleus bilaterally (arrowhead). Axial fat-suppressed T2-weighted images (G and H) reveal mild edema of the medial head of gastrocnemius (arrow) and soleus (arrow head) bilaterally. (I–N) Histological findings: (I) H&E stain: variation in fiber size, connective tissue proliferation and necrosis. (J) Gomori trichrome: connective tissue proliferation. (K–N) Positive immunostaining for MHC class I CD4, CD8 and CD68, respectively. (I–N) 10x; scale bar: 1 μ m.

Abbreviations: MHC, major histocompatibility complex; MRI, magnetic resonance imaging.

in fiber size, connective tissue proliferation and necrosis, suggesting a dystrophic pattern. Immunohistochemistry studies, including dysferlin, dystrophin, sarcoglycans, merosin, caveolin-3 and collagen VI, showed normal immunoexpression. Diffuse major histocompatibility complex (MHC) class I overexpression was observed. CD4, CD8 and CD68 were also overexpressed (Figure 1).

Based on these findings, several molecular analyses were performed, including a genetic panel of NGS containing *ANO5*, *DYSF*, *GAA*, *SGCB*, *SGCG*, *SGCA*, *SGCD*, *CAPN3*, *FKRP* and *TCAP* genes. No mutations were found.

As the progression continued, it was decided to treat the patient with prednisolone 1 g/day for 5 days, which showed clinical improvement.

After 1 year, a new muscle magnetic resonance imaging was done to assess the progression of the weakness, which revealed progressive worsening characterized by muscle atrophy and fatty infiltration of the bilateral semimembranosus and fatty infiltration and edema of the gastrocnemius and soleus muscles (Figure 2).

As she did not improve, in March 2016, we started treatment with intravenous immunoglobulin (IV Ig). As a result, the patient noticed a slight improvement in the strength of the right foot.

As all molecular results were negative, anti-SRP and anti-HMGCR antibodies were determined by enzyme-linked immune-sorbent assay (CUSABIO® kit). It was found to be negative for anti-SRP and positive for anti-HMGCR (value=7.516632, cutoff 2.283). A diagnosis of NAM was finally confirmed, but immunoglobulin therapy was stopped due to the fracture.

Unfortunately, in October 2016, she collapsed on the floor. An X-ray revealed a fracture of her right femur. She also suffered from brachial plexus palsy. She underwent surgery and was kept under complete rest for 3 months interrupting IV Ig therapy. Currently, she has started using IV Ig once a month again and is getting better every day despite the limitations resulting from the fall. Currently, she cannot lift her right arm, but is able to walk with assistance.

Ethical approval

Written informed consent has been provided by the patient to have the case details and any accompanying images published.

Discussion

We report here an adult case of anti-HMGCR antibodies-linked NAM for whom diagnosis was delayed mainly due to pathologic findings, suggesting muscular dystrophy (MD).

Figure 2 Axial muscle MRI of thighs and legs.

Notes: Thighs (A–D): diffuse edema of the right semimembranosus and tenuous edema of the left semitendinosus and femoral biceps. Legs (E–H): diffuse edema and discrete fatty infiltration of the soleus muscle and the medial and lateral heads of both gastrocnemii.

Abbreviation: MRI, magnetic resonance imaging.

There are a few reports in the literature about cases of anti-HMGCR+ myopathy previously diagnosed as MD.^{5–7} Table 1 shows the demographic and clinical characteristics of these patients.

Some points should be highlighted in this case:

- Although there were no other family members with muscle disease, the muscle biopsy findings of our patient were reminiscent of hereditary MDs, while the disease progression was faster than it usually occurs in MD.
- Careful history and examination of the patient complemented by review of the muscle biopsy showing overexpression of MHC class I associated with absence of

Table 1 Previous cases reported with anti-HMGCR myopathy simulating dystrophic-like pattern

Authors	n	Gender (M/F)	Initial presentation	Age of onset	Age of diagnosis	CK (first visit)
Mohassel et al, ⁵ 2017	1	M	Decrease in running	9 years	14 years	8,000
Tard et al, ⁶ 2017	1	F	Abnormal gait	5 years	19 years	7,576
Liang et al, ⁷ 2017	4	NO	Motor delay	10 months	NO	352–918
		NO	Asymptomatic high CK	6 years	NO	6,391
		NO	Difficulty in pedaling and climbing stairs	13 years	NO	7,183
		NO	Difficulty in climbing stairs	9 years	NO	9,570

Abbreviations: CK, creatine kinase; HMGCR, 3-hydroxy-3-methylglutaryl coenzyme A reductase; NO, not obtained.

facial weakness and extraocular muscle involvement led us to consider the possibility of an autoimmune myopathy, even in the presence of a dystrophic-like pattern on muscle biopsy.

- Although she was a healthy patient in the point of neurologic view, she had a history of significant comorbidities:

1. The patient had dyslipidemia which had been treated for 2 years with simvastatin 20 mg/day; she discontinued the medication after the onset of muscle symptoms without improvement of muscle strength.
2. In 2007, 6 years before the myopathy was diagnosed, she was diagnosed with breast cancer for which she underwent surgery and chemotherapy. They gave satisfactory results that are currently controlled.

We must remember that adults with proximal muscle weakness, elevated CK levels and features of myopathy on electromyography have a broad differential diagnosis that includes autoimmune myopathies, toxic myopathies (statin self-limited side effects, anti-retrovirus), paraneoplastic myopathies and MDs. Distinguishing between immune-mediated myopathies and other etiologies is crucial, because only autoimmune muscle diseases routinely respond to immunosuppressive therapy.⁸

According to a previous report, weakness in NAM anti-HMGCR in some cases presents an acute onset (within ≤ 4 weeks), and in a few cases, weakness could evolve slowly (from months to several years), occasionally mimicking MD, the most common and representative myopathy, being part of hereditary or sporadic progressive diseases and characterized by several phenotypic and genetic features.^{2,6,9}

In relation to autoimmune myopathies, anti-SRP-positive patients have a low incidence of pulmonary fibrosis, skin rash and arthritis as well as muscular involvement. In contrast, anti-HMGCR-positive patients usually present only muscle weakness which difficult to differentiate them from MD patients.^{9,10}

Regardless of the upregulation of MHC class I and the deposition of complement on capillaries and non-necrotic muscle fibers, which may suggest the probability of an immune-mediated process, the possibility of nonimmune-mediated myopathic processes should always be considered in patients who have a necrotizing muscle biopsy.¹⁰

Although anti-HMGCR myopathy is associated with statin exposure in patients aged 50 years, approximately one-fourth of anti-HMGCR-positive patients develop a similar myopathic process in the absence of statins, including those with self-limited statin intolerance.^{5,11} Our patient developed the symptoms during statin exposure and showed no improvement after statin withdrawal, maintaining high CK levels.

Clinical and epidemiologic data have confirmed the temporal relationship between the onset of myositis and malignancy, and cancer-associated myositis has been defined as a cancer occurring within 3 years of diagnosing myositis.¹² In addition, other studies report an increased risk of cancer up to 5 years.¹³

In 2016, Allenbach et al examined a large cohort of patients and showed for the first time that patients with NAM and anti-HMGCR antibodies were associated with an increased risk of cancer. Malignancy occurred in 17.3% (9/52) of anti-HMGCR+ patients. The mean duration between the diagnosis of cancer and myopathy was 4.2 ± 4.9 years. Two-thirds of the malignancies occurred within 3 years of or before the diagnosis anti-HMGCR+ myopathy. No specific type of cancer was observed.¹⁴

In the same year, Kadoya et al found that the prevalence of cancer within 3 years of myopathy diagnosis (cancer association) among patients with anti-HMGCR myopathy was 36% (12/33). This occurred in most patients (92%) within 1 year of myopathy diagnosis.¹⁵

On the other hand, previous large-scale studies showed prevalence rates of cancers in patients with anti-HMGCR myopathy ranging from 4% to 26% (irrespective of the temporal association between cancer detection and myopathy

diagnosis).¹⁵ Our patient had breast cancer 6 years before the beginning of symptoms.

Based on the findings, we considered the possibility of an autoimmune myopathy, which led us to initiate IV Ig that caused a mild improvement in muscle weakness. However, the IV Ig was interrupted because the patient had a fall that caused fracture.

The poor response to IV Ig may have different explanations:

- Would the HMGR myopathy be a paraneoplastic manifestation and, therefore, without indication of the immunoglobulin? There are some differences between cancer association and history of cancer, the former highlighting the importance of the successful treatment of malignancy improving the myopathy.
- Could the poor response to the immunoglobulin treatment be caused by the fracture, making it impossible for the patient to walk?
- Could the patient have a self-limited statin myopathy to NAM anti-HMGR that typically improves by immunosuppressive therapy?

However, many questions remain unanswered. The new case studies may clarify these.

In summary, the diagnosis of NAM is sometimes delayed due to the atypical pathologic findings on muscle biopsy. As the disease is a severe condition, prompt recognition can lead to a successful outcome.

We advise to consider this entity as a differential diagnosis among MDs.
