Purpose: Ipilimumab is an immune checkpoint inhibitor that is now widely used for patients with metastatic malignant melanoma. However, this immune checkpoint inhibitor can induce related adverse events in various organs. Here, we report a case of bilateral drug (ipilimumab)-induced serous retinal detachment (SRD), and the characteristic features found during swept-source optical coherence tomography (SS-OCT).

Case: A 78-year-old man with metastatic melanoma received 4 cycles of dacarbazine, nimustine, vincristine, and interferon-beta starting in January 2014, followed by 47 cycles of nivolumab starting in September 2014. Treatment with ipilimumab was started in June 2017. After 2 cycles of ipilimumab, the patient noticed impairment of the visual field in both of his eyes (at day 22) and visited our department in August 2017. Best corrected visual acuity at this initial visit was 16/20 in both eyes, while a fundus examination revealed SRD and retinal pigment epithelial detachments in both eyes. When using the horizontal and vertical 12 mm B-scanned images of SS-OCT, we detected SRD accompanied by a widely distributed high reflection of the photoreceptor outer segment, including the area where the SRD appeared. In addition, the image also showed the interdigitation zone was indistinguishable. Fluorescein angiography showed little leakage in the maculae. During his course of follow-up examinations, there was an increase in the SRD at the beginning, after which it then gradually decreased. However, the obscurity of the interdigitation zone remained.

Conclusion: Ipilimumab may cause impairment of the outer retinal layer. We suggest that this is a presumed ipilimumab-induced SRD.

Keywords: ipilimumab, metastatic malignant melanoma, serous retinal detachment

Introduction

Ipilimumab is an immune checkpoint inhibitor that is widely used in the treatment of patients with metastatic malignant melanoma. Ipilimumab blocks cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4), thereby leading to enhanced T-cell activation for the tumor. CTLA-4 also presents on the surface of regulatory T-cells, and inhibits regulatory T-cells that can lead to enhanced tumor immunity.¹ However, this immune checkpoint inhibitor can induce related adverse events in various organs. For example, systemic complications such as type I diabetes, hypothyroidism, hypopituitarism, colitis and hepatitis have been reported. Ophthalmologic complications have also been reported and include iridocyclitis, optic neuritis,² chorioretinitis and Vogt-Koyanagi-Harada-like syndrome with impaired hearing and vitiligo.³

Recently, remarkable advances in optical coherence tomography (OCT) have made it possible to detect and clearly visualize horizontal and vertical 12 mm B-scanned images.

Here, we report characteristic findings found in swept-source OCT (SS-OCT) images obtained in a case of bilateral drug (ipilimumab)-induced serous retinal detachment.

Case Report

A 78-year-old man had exanthema on his head and visited the Department of Dermatology in the general hospital in October 2009. It was removed by surgery. Pathological examinations of the removed specimens led to a diagnosis of malignant melanoma. He received a course of follow-up examinations for 4 years because the cancer did not metastasize. Then, the malignant lesions were found to have spread to the right lung, which were then removed during an additional surgery. He was subsequently diagnosed as T4aN0M1 Stage IV. Based on a second opinion, he visited the Department of Dermatology in our hospital and he elected to receive 4 cycles of dacarbazine, nimustine, vincristine, and interferon-beta starting in January 2014. After finding new metastasis in the liver and lungs, he was

additionally administered nivolumab. However, 3 months later, further metastasis to the bones, pleura, and peritoneum were found. Therefore, in June 2017, it was decided to start the patient on a new treatment with ipilimumab. He had received ipilimumab at 3mg/kg (weight of him was 55.5kg) every 3 weeks for 4 cycles according to the protocol. After 2 cycles of ipilimumab, the patient noticed impairment of the visual field in both of his eyes at 22 days after the last administration and visited our department in August.

At his initial visit, best corrected visual acuity was 16/20 in both eyes and there were no abnormal findings in either the anterior chamber or optic media. Fundus examination revealed serous retinal detachment (SRD) and several retinal pigment epithelial detachments in both eyes (Figure 1). Fluorescein angiography (Spectralis HRA+OCT; Heidelberg Engineering GmbH) revealed no obvious leakage in either of the SRD areas. Indocyanine green angiography (Spectralis HRA+OCT; Heidelberg Engineering GmbH) showed neither

Figure 1 Fundus photographs and optical coherence tomography at the initial visit. Fundus photographs of the right (A) and the left eye (B) show SRD with a 1.5 disc diameter. Vertical and horizontal SS-OCT images with a 12 mm diameter show SRD at the macula and elongation of the photoreceptor outer segments at the macula in the right (A) and left (B) eyes.

leakage during both the early and late phases nor any abnormal choroidal hyperpermeability (Figure 2). SS-OCT (Topcon DRI OCT Triton Swept Source OCT, Topcon, Japan) identified SRD accompanied by a widely distributed high reflection of the photoreceptor outer segment when using the horizontal and vertical 12 mm B-scanned images. High reflection of the photoreceptor outer segment was detected in both areas where the SRD appeared and did not appear. In normal retina, ellipsoid zone and interdigitation zone are distinguishable, however in these suffered areas, the distribution of the high reflection was not used to differentiate between the interdigitation zone and the ellipsoid zone. SS-OCT also detected thickening (maximum diameter 75 μm) of the photoreceptor outer segment (Figure 3). Fundus autofluorescence (FAF) showed there were no abnormalities (Figure 4). After this evaluation, he was administered 4 cycles of ipilimumab. During his course of follow-up examinations, initially there was a slight increase in the SRD during 4 cycles of ipilimumab, after which the SRD then gradually decreased, and the impairment of his visual field stabilized. Although best corrected visual acuity was 16/20 in both eyes, the SRD and obscurity of the interdigitation zone remained (Figure 5). He had hyperopia at the initial visit and no shift occurred during a course of follow-up examinations.

Discussion

SS-OCT performed in a case of malignant melanoma treated by ipilimumab revealed SRD in both eyes. This was accompanied by high reflection and thickening of the photoreceptor outer segment that resulted from the indistinguishability of the interdigitation and ellipsoid zones. These regions corresponded to the area where the SRD appeared and the adjacent macular area. These results suggest that ipilimumab may cause impairment of the outer retinal layer.

Several clinicians have reported on cases with ocular side effects of ipilimumab, with the typical cases of immune-related ocular side effects appearing to be similar to Vogt-Koyanagi-Harada-like syndrome.^{2,3} However, our current case did not have findings suggestive of Vogt-Koyanagi-Harada-like syndrome, nor did it have any typical angiographic findings which suggested the presence of central serous chorioretinopathy (CSC).

SS-OCT evaluations in this case did reveal characteristic images of the outer retinal layer including: 1) high reflection in the area where the SRD appeared and in the adjacent retinal area, 2) the interdigitation zone was indistinguishable in the area where the high reflection appeared, and 3) there was thickening of the photoreceptor outer segment in the same area. A previous study that used OCT to examine

Figure 2 Fluorescence and indocyanine green angiography at the initial visit. Fluorescence angiography images of the right (A and E) and the left eye (B and F) did not detect any abnormal hyperfluorescence in the macular, vessel and optic discs during both the early (A and B) and late (E and F) phases. Indocyanine green angiography images of the right (C and G) and the left (D and H) eye did not reveal any choroidal hyperpermeability or delayed perfusion during both the early (C and D) and late (G and H) phases.

Figure 3 High magnification SS-OCT images at the parafoveal area of the right (**A**) and left (**B**) eyes at the initial visit. In both the area where the SRD appeared and in the adjacent area, SS-OCT detected a high reflection of the photoreceptor outer segment while the interdigitation zone was indistinguishable (between the arrowheads). SS-OCT also detected thickening (maximum diameter 75 μ m) of the photoreceptor outer segment. The reflection of the retinal pigment epithelium line appeared to be brighter with slightly poorer margins.

CSC patients reported finding elongation of the photoreceptor outer segment in these subjects.⁴ Although elongation of the photoreceptor outer segment was also detected in our current case, the high reflection of the photoreceptor outer segment that we additionally observed in the adjacent outer retina was not seen in patients with typical CSC (Figure 6). Matsumoto et al reported that fundus granular-hyperfluorescence in SRD was observed in the FAF patterns in CSC.⁵ Even so, FAF did not identify any prominent abnormalities in our case (Figure 4). Based on these findings, it is our belief that ipilimumab was responsible for the damage in the outer retina, and this is a presumed ipilimumab-induced SRD.

It has been reported that OCT can be used in commotio retinae cases to detect thickening and high reflection of the outer part of the photoreceptor that have been recently interpreted as being the ellipsoid zone.⁶ Evaluations of histological sections from commotio retinae specimens have shown the presence of intercellular edema of the glial cells and fragmentation of the photoreceptor outer segment.^{6,7} Thus, these histological changes may correspond to the thickening and high reflection of the outer part of the photoreceptor. In addition, the swelling observed at the junction between the inner and outer segment of the photoreceptor in the retinal light damage model may cause

Figure 4 Autofluorescence at the initial visit. The right and left eye exhibited no abnormal hyperfluorescence in the macular area.

the undistinguishable detection of the retinal pigment epithelium and ellipsoid bands in the OCT images.⁸ To our knowledge, there were two reports that showed similar OCT findings to those in our case during the course of chemotherapy with immune checkpoint inhibitor for malignant melanoma.⁹ Recently, Sandhu et al reported a case of

paraneoplastic polymorphous vitelliform maculopathy during vemurafenib and pembrolizumab treatment and OCT findings were similar to those in our case.¹⁰

In our current case, the overall high reflection and thickening of the photoreceptor outer segment observed by the SS-OCT might have been due to the destruction of the photoreceptor outer segment that was potentially impaired by ipilimumab.

Although ipilimumab treatment was continued after the appearance of SRD due to the priority of dealing with the patient's general condition, his visual acuity was maintained. Ipilimumab therapy is currently only used in patients with malignant melanoma, recent indications have suggested that the use of ipilimumab will be expanded to non-small cell lung cancer, small cell lung cancer, and bladder cancer. Ophthalmic complications directly connected to ipilimumab therapy are rare, with an incidence of less than 1%.¹¹ Even so, there should be careful follow-up examinations in patients

Figure 5 Time course of the fundus photographs and the SS-OCT images during the patient's course of follow-up examinations. Fundus photographs and SS-OCT images at 1, 2, 3 and 4 months post-ipilimumab treatment. At 1 month, best corrected visual acuity was 16/20 in both eyes. SS-OCT revealed a slight increase in the height of the SRD at the central macula, compared to that found for the initial visit. The heights were 275 μm in the right (A) and 309 μm in the left (B) eye. At 2 months, the heights of the SRD in the right (C) and left (D) eyes were 323 μm and 345 μm , respectively. At 3 months, the heights were 323 μm in the right (E) and 345 μm in the left (F) eye. At 4 months, the heights were 158 μm in the right (G) and 232 μm in the left (H) eye. There were no changes noted in the patient's visual acuity during the course of follow-up examinations, with Snellen chart best corrected visual acuity of 16/20. Although the height of the SRD was reduced at 4 months, the SRD was still slightly observed. The high reflection of the photoreceptor outer segment also remained at 4 months.

Figure 6 Comparison of SS-OCT images of the outer retinal layer between normal eyes (A), our current case (B) and a patient with central serous chorioretinopathy (CSC) (C). Compared to the normal eye (A) or a case with CSC (C), our case (B) exhibited a thickened photoreceptor outer segment. The heights between the ellipsoid zone and the retinal pigment epithelium of average central zone thickness were 41 μm in the normal eye, 76 μm in our case, and 40 μm in the CSC case.

receiving ipilimumab due to a potential increase in ocular complications related to the administration of ipilimumab.

Findings for our current case suggest that ipilimumab may impair the outer retinal layer over a wide range, and thus patients being administered ipilimumab are required to undergo ophthalmic evaluations using OCT.

Ethics Statement

Written informed consent for the publication of the case details was obtained from the patient in this case report. Institutional approval was not required to publish the case details.

Publish your work in this journal

The International Medical Case Reports Journal is an international, peer-reviewed open-access journal publishing original case reports from all medical specialties. Previously unpublished medical posters are also accepted relating to any area of clinical or preclinical science. Submissions should not normally exceed 2,000 words or 4

published pages including figures, diagrams and references. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
