Purpose: Although many studies have indicated the association between low back pain (LBP) and lifestyle factors, the combined effect of lifestyle factors on LBP has not been adequately investigated. We aimed to investigate the association between a cluster of unhealthy lifestyle behaviors and LBP using a large cohort of Japanese adults.

Methods: We included 419,003 adults aged over 20 years who underwent an annual health checkup between April 2013 and March 2014 in Japan. Information on the following lifestyle factors was collected using the standardized questionnaire: smoking, alcohol intake, exercise, physical activity, walking speed, weight control, eating habits, and sleep. Each factor was evaluated as a dichotomous variable (1: health risk, 0: no health risk). A lifestyle risk score was calculated by summing the score of each lifestyle factor (range: 0–12) and was categorized into three groups (low, moderate, high). LBP was defined as self-reported LBP under treatment. Logistic regression analysis was conducted to calculate the odds ratio (OR) and 95% confidence interval (CI) for LBP.

Results: In multivariable logistic regression analysis, the OR for LBP was significantly higher in the moderate-risk score group (adjusted OR: 1.33 [95% CI: 1.23–1.44] in men; 1.40 [95% CI: 1.27–1.54] in women) and the high-risk score group (adjusted OR: 1.54 [95% CI: 1.43–1.67] in men; 1.83 [95% CI: 1.64–2.03] in women) than in the low-risk score group. A trend of higher risk of LBP associated with higher lifestyle risk score was observed in both sexes (p for trend < 0.001). These results were similar even in subgroup analysis by age and body mass index (BMI).

Conclusion: Clustering of unhealthy lifestyles was associated with increased risk of LBP regardless of age and BMI. These results may provide implications for better prevention and management of LBP, considering modifiable lifestyle factors.

Keywords: lifestyle, low back pain, clustering, health checkup

Introduction

Low back pain (LBP) is one of the primary causes of disability and remains a major health problem worldwide.¹ LBP has an enormous economic burden including direct and indirect costs such as loss of work productivity.² Previous epidemiological studies have indicated a number of multidimensional risk factors for LBP.³ Among these, lifestyle factors are a particularly important domain as they are potentially modifiable. In fact, targeting lifestyle as part of the management of LBP has been recommended.^{4,5}

The impact of lifestyle factors such as smoking, physical activity, alcohol, and diet on health outcome has been extensively studied. This impact, mainly on

Correspondence: Takahiko Yoshimoto
Email yoshimotot@med.showa-u.ac.jp

cardiovascular disease,⁶ diabetes,⁷ cancer,⁸ and mortality,⁹ has been shown to be especially greater when the factors were accumulated. Therefore, evaluating the cluster of lifestyle factors is considered important to prevent the negative effects on health.

The development and chronicity of LBP have been considered to be linked to lifestyle factors. A population-based study using data from National Health and Nutrition Examination Survey indicated that smoking, physical activity, and obesity were associated with LBP.¹⁰ Similarly, many studies investigated the association of LBP with each lifestyle factor such as smoking, physical inactivity, alcohol consumption, and sleep disturbance.^{11–14} However, the combined effects of lifestyle risk factors on LBP have not been adequately investigated. In particular, studies for Asian population who has a bit different lifestyle from Western population are very scarce. Elucidating the effect of the accumulation of lifestyle factors on LBP may help to demonstrate the importance of lifestyle modification for the prevention or management of LBP. Therefore, we investigated the association between the clustering of multiple lifestyle factors and LBP using a large-scale, cross-sectional data in Japan as the primary objective. Moreover, if the association was found, we evaluated the effects of age and body mass index (BMI) on the association. We hypothesized that the accumulation of unhealthy lifestyle factors is associated with increased risk of LBP because lifestyle behaviors consist of multiple dimensions that coexist and are mutually related in many cases.^{15,16}

Methods

Study Population

This was a cross-sectional study that used health checkup data. The check-up was conducted by the All Japan Labor Welfare Foundation, a health checkup center in Japan. A health checkup is mandatory for all employees in Japan at least once a year under the Industrial Safety and Health Act. Subjects were almost Japanese workers but included a small number of their dependents and foreign workers. Eligible subjects in the present study were adults aged over 20 years who underwent the annual health checkup between April 2013 and March 2014. Of the 552,005 subjects, 551,871 subjects consented to participate in this study. Of these, we excluded 132,868 subjects with missing data on any variables used in the present study. Thus, 419,003 participants were included in the analysis. Written informed consent for the use of personal

health checkup data in this study was obtained from each participant. This study protocol was approved by the Ethics Committee of the All Japan Labor Welfare Foundation (Approval No. 9-1-0007) and the medical ethics committee of Showa University School of Medicine (Approval No. 2407).

Study Measures

Data on age, sex, lifestyle behaviors, medical history, and current use of medications were collected using a self-administered questionnaire. Trained staff measured height to the nearest 0.1 cm using a stadiometer and weight to the nearest 0.1 kg using a scale. BMI was calculated as weight (kg) divided by the square of height (m). Blood pressure was measured in the sitting position using an automated sphygmomanometer (HEM-907, Omron, Kyoto, Japan). LBP was defined as self-reported LBP under treatment (ie, a “yes” answer to the question “Do you have LBP under treatment including follow-up?”).¹⁷

Blood samples were collected and stored in a cooler at 4°C for transporting to an external laboratory (SRL, Tokyo, Japan). Triglyceride levels were measured using an enzymatic method (AU5400; Beckman Coulter, Tokyo, Japan), while low-density lipoprotein cholesterol (LDL-C) and high-density lipoprotein cholesterol (HDL-C) were measured using a direct method (AU5400; Beckman Coulter, Tokyo, Japan). Hemoglobin A1c (HbA1c) level was determined using latex agglutination turbidimetry (JCA-BM9130, JEOL, Tokyo, Japan).

Hypertension was defined as systolic blood pressure \geq 140 mmHg, diastolic blood pressure \geq 90 mmHg, or medication use for hypertension.¹⁸ Diabetes was defined as HbA1c (National Glycohemoglobin Standardization Program) \geq 6.5% or medication use for diabetes.¹⁹ Dyslipidemia was defined as triglyceride \geq 150 mg/dL, HDL-C $<$ 40 mg/dL, LDL-C \geq 140 mg/dL, or medication use for dyslipidemia.²⁰

Assessment of Lifestyle Risk Score

Questionnaire items on lifestyle behaviors were based on the standardized questionnaire used for the National Health Promotion Program,^{21,22} which started in Japan in 2008 and aimed to prevent lifestyle-related diseases (eg, metabolic syndrome and cardiovascular disease). The following 12 items related to lifestyle behaviors were used in the present study: 1) smoking habits (current, former, none), 2) alcohol intake (everyday, sometimes, none), 3) exercise \geq 30 min/day, \geq twice a week, and \geq 1 year (yes, no), 4) physical activity equal to walking \geq 60 min/day

(yes, no), 5) walking faster than others in the same generation (yes, no), 6) weight gain ≥ 10 kg since age 20 years (yes, no), 7) body weight change ≥ 3 kg during the preceding 1 year (yes, no), 8) eating speed (fast, normal, slow), 9) eating dinner within 2 hours before bed \geq three times per week (yes, no), 10) having a snack after dinner \geq three times per week (yes, no), 11) skipping breakfast \geq three times per week (yes, no), and 12) adequate sleeping (yes, no).

For each lifestyle factor, we created a binary variable; 1 represented health risk (unhealthy) and 0 showed no health risk. The criteria of health risk were determined with reference to the recommended guideline or current health-related studies.^{7,23-29} Specifically, we assigned a score of 1 for each item as follows: 1) current smoking, 2) drinking alcohol every day, 3–5) a response of no, 6–7) yes, 8) eating fast, 9–11) yes, and 12) no response. A lifestyle risk score was calculated by combining the scores of the 12 lifestyle factors (range: 0–12)¹⁹ and was categorized into the following three groups by tertile of the total score; low (score: 0–3), moderate (4–5), and high risk (6–12).

Statistical Analysis

Data on the participants' characteristics are presented as n (%), or median (25th, 75th percentiles) and mean (standard deviation). Characteristics of the study participants with and without LBP were compared using chi-squared test for categorical variables or Wilcoxon rank-sum test for continuous variables.

To evaluate the association between LBP and lifestyle risk levels, a logistic regression analysis was performed to calculate the odds ratio (OR) and 95% confidence interval (CI) for LBP. Model 1 was a crude model, and model 2 was adjusted for age and BMI (as continuous variables). Model 3 was further adjusted for hypertension, diabetes, and dyslipidemia (as dichotomous variables). We then examined the association between LBP and lifestyle risk score stratified by age (20–39, 40–59, and ≥ 60 years) and BMI (underweight: < 18.5 , normal weight: 18.5–24.9, and overweight/obesity: ≥ 25 kg/m²) categories in model 3. Multiple co-linearity was not suspected in the analysis, with all variance inflation factors (VIFs) were < 2 . Test for trend was conducted with the lifestyle risk score groups considered as continuous variables. All statistical analyses were performed using SAS software version 9.4 (SAS Institute Inc., Cary, NC,

USA). A p value < 0.05 was considered statistically significant.

Results

The median age (25th, 75th percentile) of the study participants was 45 (range, 36, 55) years, and 67.1% of the participants were men. The prevalence of LBP under treatment was almost 2% ($n = 8061$) of the total population. Comparison of the participants' characteristics according to LBP is shown in Table 1 for men and Table 2 for women. Individuals with LBP were older, had higher BMI, and were more likely to have hypertension, diabetes, and dyslipidemia than those without LBP in both sexes.

Table 3 shows the association between lifestyle risk score (low, moderate, and high) and LBP by sex. In both sexes, the age- and BMI-adjusted OR for LBP were higher in the moderate risk score group (OR: 1.32 [95% CI: 1.22–1.43] in men; OR: 1.39 [95% CI: 1.27–1.54] in women) and the high-risk score group (OR: 1.53 [95% CI: 1.42–1.65] in men; OR: 1.81 [95% CI: 1.63–2.02] in women) compared with those in the low-risk score group. Further adjustment for hypertension, diabetes, and dyslipidemia did not markedly change the association of LBP with the lifestyle risk score.

Table 4 shows the association between LBP and lifestyle risk score by age groups. In all age categories, compared to individuals with low-risk score, the ORs for LBP in the moderate and the high-risk score groups were significantly increased. A trend of higher risk of LBP associated with higher lifestyle risk score was observed in both sexes and all age groups (p for trend < 0.001 in all).

We also performed BMI-stratified analysis for the association between lifestyle risk score and LBP (Table 5). Among underweight men, only the high-risk score group showed higher OR for LBP (adjusted OR: 1.66 [95% CI: 1.15–2.38]). Meanwhile, among underweight women, higher ORs for LBP were observed in the moderate risk score group (adjusted OR: 1.43 [95% CI: 1.05–1.95]) and the high-risk score group (adjusted OR: 1.68 [95% CI: 1.13–2.50]). Among subjects with normal weight or overweight/obesity, LBP was significantly associated with lifestyle risk score in the moderate risk score group and the high-risk score group. There were significant dose-response relationships between the level of lifestyle risk score and LBP in all BMI strata (p for trend < 0.01 in all).

Discussion

We previously revealed the relationship of metabolic syndrome with LBP among middle-aged Japanese adults.³⁰ However, individual components of metabolic syndrome are significantly affected by various lifestyles. In the present study, we investigated the association between the clustering of multiple unhealthy lifestyle behaviors and LBP among all adults using a large-scale health checkup data in Japan. We found that a combination of unhealthy lifestyle behaviors was dose-dependently associated with increased risk of LBP in both sexes. These associations were observed regardless of age and BMI status. To our knowledge, this is the first study demonstrating the influence of unhealthy lifestyle clustering, which included multifaceted lifestyle factors, on LBP in Japanese adults.

In this study, focusing on the clustering of multiple lifestyle risk factors, we evaluated unhealthy lifestyle factors using 12 questionnaire items that have been recommended for use by the National Health Promotion Program in Japan.^{21,22} These factors included Breslow's health habits including smoking, alcohol drinking, physical activity, weight control, breakfast, snacking, and sleep.³¹

Previous studies investigated the relationship between healthy lifestyle behaviors and LBP using a limited number of lifestyle factors,^{32–34} and indicated that health lifestyle behaviors may decrease the risk of developing LBP, although there may be sex- or age-related differences in the effects. It is difficult to directly compare our results with previous findings because the definition of health lifestyle behaviors varies by studies. For example, a previous study defined health behavior using information on BMI, physical exercise, and smoking.³³ However, our findings were consistent with those of previous studies. Our results that clustering of unhealthy lifestyles could negatively influence LBP may have important implications for the prevention and management of LBP both in a public health and a clinical perspective.

Age is one of the common risk factors for LBP. A previous systematic review has demonstrated that the prevalence of severe LBP increases with age.³⁵ Although several lifestyle behaviors were also expected to vary depending on age, our age-stratified analyses indicated the dose-response relationship between accumulation of unhealthy lifestyle risk and LBP regardless of age groups

(20–39, 40–59, and ≥ 60 years). These findings suggest the importance of education related to healthy lifestyle for preventing LBP throughout the adult population.

Previous systematic reviews with meta-analysis have shown that overweight and obesity increased the risk of LBP.^{36,37} Moreover, many of the unhealthy lifestyle

factors included in the present study have been considered to be associated with overweight/obesity.^{23,24,26,28}

Therefore, to eliminate the effects of BMI status on LBP, we analyzed the association of LBP with lifestyle risk according to BMI strata (underweight, normal, and overweight/obesity). This stratified analysis showed that

moderate and high lifestyle risk scores were significantly associated with increased risk of LBP among all individuals except for underweight men. Moreover, regardless of BMI status, the accumulation of unhealthy lifestyle risk factors resulted in a significantly higher OR for LBP (*p* for trend < 0.01). These results imply that improving unhealthy lifestyle behaviors may prevent the development of LBP even in non-overweight individuals.

No simple explanation can be given with regard to the potential mechanism behind the association of unhealthy lifestyle clustering with risk of LBP. Unhealthy lifestyle may affect LBP through biological processes such as vascular degeneration. For example, metabolic disturbance caused by unhealthy lifestyle could induce the atherosclerotic change in the artery, which may lead to the degeneration of the lumbar intervertebral disc.³⁸ Even individuals without obesity have been indicated to readily

develop metabolic disturbances,³⁹ which might support our results in the BMI-stratified analysis. The other possible explanation is the involvement of psychological aspects. Several studies have indicated that lifestyle factors are associated with mental health, which may be bidirectional.^{40,41} From a perspective in the biopsychosocial model, unhealthy lifestyle factors may affect the increased risk of LBP through psychological problems. Further, high levels of health literacy have been indicated to be associated with healthy lifestyle.⁴² A previous study has emphasized the importance of addressing the health literacy in the self-management for LBP.⁴³ Further investigations are needed with regard to these points.

Our study indicated that the prevalence of LBP under treatment was almost 2% in total participants. The low prevalence may be due to the definition of LBP used in this study. We used LBP under treatment as the outcome of interest according to a previous study.¹⁷ The outcome may mean to be individuals with severe or disabling LBP. The Comprehensive Survey of Living Conditions, conducted by the Ministry of Health, Labour and Welfare in Japan, indicated the prevalence of backache under treatment was 5.25% in which elderly individuals with high prevalence of LBP were included.¹⁷ Also, a previous study showed that the prevalence of LBP treated was 3.2% among health examinees aged 40–59 years,⁴⁴ which was similar to our results.

The strength of this study was the large-scale sample size that helped reduce the random error and could permit exploring the risk along multidimensional aspects of lifestyle factors. However, the present study also has several limitations. First and foremost, the lack of longitudinal data is a shortcoming that prevents us from determining the direction of the links between LBP and the clustering of lifestyles. LBP could have negative effects on healthy lifestyles such as exercise or sleep. Further prospective studies are warranted to establish the causal relationship between the accumulation of unhealthy lifestyles and LBP. Second, the determination of LBP relied on self-reports and was not based on clinical examinations. Differentiating LBP type (eg, acute pain or chronic pain, or localized pain or radicular pain, disease-specific) might have been helpful to explore the associations found here in more detail. Third, we performed analyses assuming that there is no interaction between each lifestyle factor in this study. Although we used the same methods as a previous study,¹⁹ it will be necessary to assess the interaction between lifestyle factors for accurately estimating the

combined effects of lifestyles on LBP in future studies. Fourth, we cannot rule out the effects of unmeasured confounders (eg, occupation type, contents of diet, education level, or psychological status).³ In addition, although participants in this study were almost workers, we could not obtain work-related information such as type of the industry, working time, and shift pattern. This might limit the generalizability of our results. Finally, we evaluated information on lifestyle factors using a self-reported questionnaire, which is prone to social desirability bias. This could lead to misclassification of exposure; the misclassification is considered non-differential in its nature, which may have resulted in dilution of a true association.

Conclusions

In summary, we investigated the combined effects of multiple unhealthy lifestyle behaviors on LBP among more than 400,000 Japanese adults. Our results indicated that the accumulation of unhealthy lifestyle factors was associated with increased risk of LBP, and this was consistent across age and BMI status. These findings may provide important implications for the better prevention and management of LBP considering modifiable lifestyle factors.

Data Sharing Statement

The data used in the current study are available on reasonable request and with permission of the Ethics Committee of the All Japan Labor Welfare Foundation.

Ethics Approval and Informed Consent

The present study was approved by the medical ethics committee of Showa University School of Medicine (Approval No. 2407) and the Ethics Committee of the All Japan Labor Welfare Foundation (Approval No. 9-1-0007). Written informed consent was obtained from each subject.

Acknowledgments

The authors thank Dr. Nobuo Yanagisawa, Dr. Takeshi Kawaguchi, Mr. Takahiro Tamura and Mr. Yutaka Hoshina in the All Japan Labor Welfare Foundation for their support.

Funding

This study was supported in part by the Grant-in-Aid for Young Scientists (JP18K17979) from the Ministry of

Education, Culture, Sports, Science, and Technology of Japan.

Dovepress

Publish your work in this journal

The Journal of Pain Research is an international, peer reviewed, open access, online journal that welcomes laboratory and clinical findings in the fields of pain research and the prevention and management of pain. Original research, reviews, symposium reports, hypothesis formation and commentaries are all considered for publication. The manuscript

management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
