Purpose: Despite the extensive development of antibacterial biomaterials, there are few reports on the effects of materials on the antibacterial ability of the immune system, and in particular of neutrophils. In this study, we observe differences between the in vivo and in vitro anti-infective efficacies of silver nanoparticles (AgNPs). The present study was designed to further explore the mechanism for this inconsistency using ex vivo models and in vitro experiments.

Methods: AgNPs were synthesized using the polyol process and characterized by transmission electron microscopy and X-ray photoelectron spectroscopy. The antibacterial ability of AgNPs and neutrophils was tested by the spread-plate method. The infected air pouch model was prepared to detect the antimicrobial ability of AgNPs in vivo. Furthermore, blood-AgNPs-bacteria co-culture model and reactive oxygen species (ROS) measurement were used to evaluate the effect of AgNPs to neutrophil-mediated phagocytosis and ROS production.

Results: The antibacterial experiments in vitro showed that AgNPs had superior antibacterial properties in cell compatible concentration. While, AgNPs had no significant antibacterial effect in vivo, and pathological section in AgNPs group indicated less neutrophil infiltration in inflammatory site than *S. aureus* group. Furthermore, AgNPs were found to reduce the phagocytosis of neutrophils and inhibit their ability to produce ROS and superoxide during ex vivo and in vitro experiments.

Conclusion: This study selects AgNPs as the representative of inorganic nano-biomaterials and reveals the phenomenon and the mechanism underlying the significant AgNPs-induced inhibition of the antibacterial ability of neutrophils, and may have a certain enlightening effect on the development of biomaterials in the future. In the fabrication of antibacterial biomaterials, however, attention should be paid to both cell and immune system safety to make the antibacterial properties of the biomaterials and innate immune system complement each other and jointly promote the host's ability to resist the invasion of pathogenic microorganisms.

Introduction

The infection of orthopedic implants, including open reduction and internal fixation of fractures (ORIF) and periprosthetic joint infection (PJI), is a common clinical complication, which may lead to implant failure and relapse, with a rate as high as 2%-5%.^{1,2} Implant infections are not only a heavy burden on the quality of life of patients but also constitute a huge economic burden on individuals and society.³

Furthermore, in recent years, with the prevalence of multi-drug-resistant (MDR) strains, there is no doubt that traditional antibiotic treatment is limited.⁴

As a solution to the antibiotic resistance problem, inorganic antibacterial agents, including silver,⁵ copper,⁶ gold,⁷ zinc⁸ and their nanoparticles, which have good chemical stability and are not associated with drug resistance, have emerged as alternatives to antibiotics. These antibacterial agents and the development and fabrication of more effective antibacterial biomaterials have attracted wide attention from researchers worldwide. However, these antimicrobial agents often have poor biocompatibility, which can cause cytotoxicity at very low concentrations⁹ and inhibit the immune function of the host.^{10,11} This is disadvantageous for the prevention of infection. In view of this, it is necessary to develop safer methods for antibacterial functionalization of implant surfaces.

Upon biomaterial implantation into the body, the host immune system initiates a series of responses, including the rapid adhesion of proteins in blood or tissue fluid to the surface of the implant and the activation of surrounding immune cells.^{12,13} As a key component of the host immune system,¹⁴ polymorphonuclear neutrophils (PMNs) migrate to the inflammatory site to engulf and kill pathogens when pathogenic microorganisms invade the host.¹⁵ Neutrophils exhibit superior antibacterial activity through their unique inherent properties, including phagocytosis, production of reactive oxygen species (ROS), degranulation, and formation of extracellular trapping networks (NETs).^{16,17} Furthermore, neutrophils play a crucial role in the recruitment of other immune cells to the infected site by releasing chemokines and cytokines.¹⁸ These processes are activated in the presence of foreign bodies such as implants. With sustained stimulation, the neutrophils in the surrounding vessels are continuously recruited, leading to the secretion of higher concentrations of proteolytic enzymes and ROS production, which aggravate the local inflammatory response causing tissue damage at the implantation site.^{19,20} Thus, the immune response of the host to the implant directly determines the success or failure of the implant, and the external intervention that can effectively affect the antibacterial properties of neutrophils is bound to further influence the host's ability to resist pathogen invasion.^{21–23} In other words, it is necessary to explore the effects of biomaterials with good antibacterial activity or potential on immune cells, and particularly on neutrophils. That is, in addition

to cellular safety, “the immune system safety” of biomaterials is equally important.

As inorganic metal nanoparticles possessing the unique properties of small size and high surface area to volume ratio, AgNPs are widely used in the fabrication and modification of orthopedic biomaterials because of their superior broad-spectrum antibacterial capability and their ability to reduce microbial resistance.^{24–26} Previous studies have focused solely on the interaction between biomaterials and bacteria.^{5,24,27} Although some articles have studied the effects of silver nanoparticles on the biological characteristics of neutrophils,^{11,28,29} they have not systematically examined the antibacterial properties of silver nanoparticles in vivo and in vitro and the phenomenon of their interaction with bacteria and neutrophils, especially on the underlying mechanism.

In this study, we explored the effects of AgNPs on the antimicrobial ability of neutrophils in vitro in the presence of bacteria and constructed a rat infected air pouch model to explore its effect on the host's anti-infection ability in vivo (Figure 1). Furthermore, we established immune cell-bacteria-AgNPs coculture ex vivo models (Figure 2) to study the potential influence of AgNPs on host immunity.

Materials and Methods

Synthesis of AgNPs

Twenty milliliters of glycol were placed in a three-port flask and heated to a specified temperature by placing it in a silicone oil bath, while stirring using magnetic force. Then, 10 mL of 0.1 mol/L AgNO₃ glycol solution was added to the above preheated glycol solution. AgNO₃ was obtained from Maoguo Nano Technology Co, Ltd (Shanghai, China). Next, the PVPK30 glycol solution was slowly dripped into the above solution (completed in 5 min). Finally, the product was transferred into a centrifuge tube and washed with anhydrous ethanol, before it was centrifuged and separated at 8000 rpm for 10 min in a high-speed centrifuge 4–5 times to remove the PVP adsorbed on the surface.

Characterization of the Silver Nanoparticles

Transmission electron microscopy (TEM) (JEOL JSM-IT200, Japan) was used to observe the particle size and morphology, while the chemical element composition and state of AgNPs were measured by X-ray

Figure 1 Schematic illustration of AgNPs inhibition to the antibacterial behavior of PMNs.

photoelectron spectroscopy (XPS; Thermo Scientific Escalab 250Xi, US).

Isolation of Human PMNs

Before venous blood collection from each volunteer, a standard protocol was approved by the Ethics Committee of Shanghai Jiaotong University Affiliated Sixth People's Hospital (Approval No: 2020-KY-118 (K)), and informed consent was obtained from each healthy adult volunteer, and this study was conducted in accordance with the Declaration of Helsinki. PMNs were isolated from the heparinized venous blood using a human peripheral blood neutrophil separation kit (Solarbio, Beijing, China). Trypan blue staining was used to ensure the activity of the isolated neutrophils.

In vitro Cytotoxicity Evaluation

PMNs (5×10^5 cells per well) were incubated with various concentrations (0.5 $\mu\text{g/mL}$, 1 $\mu\text{g/mL}$, 2 $\mu\text{g/mL}$, and 4 $\mu\text{g/mL}$) of AgNPs in complete RPMI 1640 medium (HyClone, USA) for 4 h. Then, the co-culture medium of each well was replaced with 0.1 mL of serum-free RPMI 1640 medium

containing 10 μL of CCK-8 solution (Dojindo Kagaku Co, Kumamoto, Japan), followed by incubation for 1 h. Next, the absorbance of the incubated solution system was determined at 450 nm using a microplate reader (Thermo Scientific, USA). Furthermore, lactate dehydrogenase (LDH) assays were used to determine the cellular activity of PMNs using the LDH cytotoxicity kit (Beyotime, Shanghai, China) according to the manufacturer's protocol. In addition, after coculture with AgNPs for 4 h, PMNs were fixed with 4% paraformaldehyde for 10 min and permeabilized with 0.1% Triton-X for 5 min, and then stained with TRITC-phalloidin and Dapi (Servicebio, Wuhan, China) for 30 and 10 min, respectively. Fluorescent images were obtained using a fluorescence microscope (Leica, Hamburg, Germany).

Preparation and Characterization of Bacteria

In this study, gram-positive *Staphylococcus aureus* (*S. aureus*) (ATCC 43300) was obtained from the American Type Culture Collection (Rockefeller, MD) in

Figure 2 Schematic illustration of ex vivo experiment.

freeze-dried form. The bacteria were cultured on sheep blood agar (SBA) plates at 37 °C overnight. Then, a single bacterial colony was carefully transferred to 3 mL of TSB and incubated on an orbital shaker for another 12 h. The purified bacterial solution was gradient diluted to a suitable concentration for in vitro and in vivo experiments.

In vitro Antibacterial Ability of AgNPs and Antibacterial Capability of PMNs Treated by AgNPs

After a single bacterial colony was incubated overnight, the bacterial suspension was diluted to a concentration of 1×10^5 CFU/mL and used to perform in vitro antimicrobial experiments. One milliliter of bacterial fluid (1×10^5 CFU/mL) was incubated with different concentrations (0.5 $\mu\text{g/mL}$, 1 $\mu\text{g/mL}$, and 2 $\mu\text{g/mL}$) of AgNPs in a 24-well plate in a bacteriological incubator for 4 h. Afterwards, the spread-plate method³⁰ was used to evaluate the survival rates of bacteria in each group, and the bacteria count was further expressed as \log_{10} CFU. To investigate if the antibacterial ability of human PMNs was affected by AgNPs, 1 mL of 10^5 cells/mL PMNs was added to 24-well plates and pretreated with different concentrations (0 $\mu\text{g/mL}$, 0.5 $\mu\text{g/mL}$, 1 $\mu\text{g/mL}$, and 2 $\mu\text{g/mL}$) of AgNPs for 2 h, the mixed system containing PMNs and AgNPs was collected and centrifuged, the supernatant was then removed. PMNs were then resuscitated by 900 μL PBS and mixed with 100 μL of 1×10^6 CFU/mL bacterial suspension, the gradient

dilution and the spread-plate method were used to count bacteria and calculate the number of planktonic bacteria.

In vivo Air Pouch Model Preparation

All animal experiments were approved by the Animal Care and Ethics Committee of Shanghai Jiaotong University Affiliated Sixth People's Hospital (Approval No: DWLL2020-0614) and carried out in accordance with the guidelines for the care and use of laboratory animals. *S. aureus*-infected air pouches were established in 2-month-old female Sprague-Dawley (SD) rats. Before the operation, the rats were anesthetized using an intraperitoneal injection of pentobarbital, followed by shaving and sterilizing the skin of the air pouch. To establish the air pouch model, 20 mL sterilized air was subcutaneously injected into the backs of the rats at day 0 and 10 mL at day 3. Subsequently, the rats were divided into four groups (n=8): control group, 1 $\mu\text{g/mL}$ AgNPs + *S. aureus* group, 2 $\mu\text{g/mL}$ AgNPs + *S. aureus* group, and *S. aureus* group. Then, Aseptic saline and 1×10^7 CFU/mL bacterial solution alone or together with either 1 $\mu\text{g/mL}$ AgNPs or 2 $\mu\text{g/mL}$ AgNPs were subcutaneously injected into the air pouch in a total volume of 2 mL, and the rats were observed for 24 h.

In vivo Antibacterial Assessment

To investigate the antibacterial ability of AgNPs in vivo, 24 h after the air pouch model was established, five rats of

each group were euthanized, and the tissue around the air pouch was aseptically cut off, weighed, and then collected using 1 mL of sterile PBS. Subsequently, the tissue was snap frozen, pulverized under sterile conditions, and, then, tissue homogenates were prepared to calculate the number of bacteria in each group using the spread-plate method.

Cytokine Level Measurement in in vivo Lavage Fluid

Before three rats in each group were sacrificed, the air pouch was injected and rinsed with 5 mL of sterile PBS, and then, the cytokine levels in the collected lavage fluid were measured using ELISA kits (Antigenix, USA).

Histological Evaluation

After three rats in each group were sacrificed, the tissue consisting of the air pouch and surrounding soft tissue was cut off, imaged, and fixed with 10% formalin. The specimens were then gradient dehydrated with ethanol and embedded in paraffin. Sections, obtained using a sledge microtome (Leica, Hamburg, Germany), were stained with hematoxylin and eosin (H&E) and Giemsa staining. Inflammatory cell infiltration and bacterial infection were observed using optical microscopy (Nikon, Japan).

Blood-AgNPs-Bacteria Co-Culture Model

To establish the blood-AgNPs-bacteria co-culture model,³¹ 500 μ L of heparinized venous blood was mixed gently with *S. aureus* (1×10^7 CFU/mL) at a ratio of 9:1, and various concentrations (0 μ g/mL, 0.5 μ g/mL, 1 μ g/mL, and 2 μ g/mL) of AgNPs. Then, the mixtures were added to the wells of a sterile 24-well plate and were incubated at 37 °C for 90 min. To investigate the survival rates of bacteria in the mixture, after coculture for 90 min, the spread-plate method was used to calculate the viable bacteria in each experimental group, which was expressed as \log_{10} CFU. To further detect PMN phagocytosis in human blood, blood smears were prepared at each designated coculture time point (0, 15, 30, 60, and 90 min), stained with Wright–Giemsa stain and observed using optical microscopy. Furthermore, to quantitatively evaluate the phagocytic ability of PMNs, the number of phagocytosed bacteria, bound bacteria, and free bacteria within a 10 μ m radius of each PMN were counted in six independent microscopic fields. The phagocytosis rate (%) = (phagocytosed bacteria count/total phagocytosed bacteria, bound bacteria, and free bacteria) \times 100.

Isolated Human Neutrophil-AgNPs-Bacteria Coculture Model

Isolated PMNs were cocultured with different dosages (0.5 μ g/mL, 1 μ g/mL, and 2 μ g/mL) of AgNPs and 1×10^7 CFU/mL bacteria. After incubation for 2 h, the PMN lysis rate of each group was measured using the LDH cytotoxicity kit (Beyotime, Shanghai, China) as mentioned above.

The Effect of AgNPs on Human PMNs ROS Production

Fluorescence detection of ROS was performed using the Reactive Oxygen Species Assay Kit (Beyotime, Shanghai, China). Different concentrations of AgNPs (0.5 μ g/mL, 1 μ g/mL and 2 μ g/mL) were incubated with 0.5 mL of 10^5 cells/mL PMNs and 50 μ L of 1×10^7 CFU/mL bacterial suspension in a 24-well plate for 1.5 h. Next, 2-7-dichlorodiacetate (DCFH-DA) fluorescent dye diluted in PBS was added to each plate and stained for 30 min. Then, the cells were washed with PBS three times, followed by fixation with 4% paraformaldehyde for 10 min. The fluorescence produced by the cells was observed using an inverted fluorescence microscope, and fluorescence quantification was detected using a fluorescence microplate reader (Thermo Scientific, USA).

The Effect of AgNPs on the Production of Superoxide by Human PMNs

Superoxide production in each group was detected using a superoxide assay kit (Beyotime, Shanghai, China). Briefly, 1×10^5 PMNs were suspended in 0.2 mL of superoxide detection working liquid and incubated with different AgNP concentrations (0.5 μ g/mL, 1 μ g/mL and 2 μ g/mL) and 10 μ L of 1×10^7 CFU/mL bacterial suspension in a 96-well plate for 2 h. Then, the absorbance of each cultured system was measured at 450 nm.

The Effect of AgNPs on Human PMNs Migration

Briefly, 10^5 PMNs/mL suspended in 0.2 mL complete RPMI 1640 medium were added to the upper chamber of a 24-well transwell plate (Corning, USA; pore size = 3 μ m), and then 0.5 mL complete RPMI 1640 medium containing different concentrations of AgNPs and 1×10^6 CFU/mL bacterial solution was added into the lower chamber. After incubation for 2 h, the cells on the upper

surface of the membrane were gently removed via a cotton swab, and the cells that migrated to the lower surface of the membrane were first fixed with 4% paraformaldehyde and then stained with 0.5% crystal violet for 10 min.

The Effect of AgNPs on Human PMNs Cytokine Production

PMNs (1 mL of 1×10^6 cells/mL) were incubated with different concentrations of AgNPs (0.5 $\mu\text{g/mL}$, 1 $\mu\text{g/mL}$ and 2 $\mu\text{g/mL}$) and 0.1 mL of 1×10^7 CFU/mL bacterial suspension for 4 h in 24 well plates, and then, the culture medium was collected, and centrifuged. The supernatants were extracted, and the cytokine levels, including those of IL-1 β , IL-6, and MCP-1, were measured using ELISA kits (Anogen, Canada).

Quantitative Real-Time PCR (RT-PCR) Analysis

PMNs (1 mL of 3×10^6 cells/mL) were cocultured with various concentrations of AgNPs (0.5 $\mu\text{g/mL}$, 1 $\mu\text{g/mL}$, and 2 $\mu\text{g/mL}$) and 0.1 mL of 1×10^7 CFU/mL bacterial suspension for 4 h, centrifuged, and washed twice with PBS. The EZ-press RNA Purification Kit (EZBioscience, USA) was used for total RNA extraction after a 5-min incubation on ice. Subsequently, the extracted total RNA was reverse-transcribed into cDNA by using a 4 \times Reverse Transcription Master Mix (EZBioscience, USA) according to the standard protocol. RT-qPCR experiments were performed using the EZBioscience 2 \times SYBR Green qPCR Master Mix and the Q7 Real-Time PCR System (Applied Biosystems, USA). The following primer sequences were used: IL-6 (forward: 5'-AACAACCTGAACCTTCCAAAG-3', reverse: 5'-CAAACCTCAAAGACCAGTGA-3'), TNF- α (forward: 5'-CAGGACTTGAGAAGACCTCAC-3', reverse: 5'-GTCTGGAAACATCTGGAGAGA-3'), IL-1 β (forward: 5'-GATATGGAGCAACAAGTGGT-3', reverse: 5'-AGGACAGGTACAGATTCT TTTC-3').

Statistical Analysis

The data from in vitro and in vivo experiments were expressed as the mean \pm standard deviation. One-way ANOVA was used to evaluate the statistical significance of the results (GraphPad Prism5, La Jolla, CA), and a P value of < 0.05 was considered statistically significant.

Results

Characterization of AgNPs

The morphology of AgNPs was examined using TEM analysis, and the results shown in Figure 3A, demonstrated that AgNPs were spherical in shape with an effective diameter of 17.9 ± 7.8 nm, and the size distribution was analyzed by counting more than 300 nanoparticles and indicated in Figure 3B. X-ray photoelectron spectroscopy of AgNPs was shown in Figure 3C and D. The binding energies of Ag 3d_{3/2} and Ag 3d_{5/2} were at 373.97 and 367.96 eV, respectively, which represent the characteristic signals of Ag, demonstrating the presence of this noble metal.

Evaluation of AgNPs Cytotoxicity in vitro

The biocompatibility of AgNPs was evaluated using PMNs. As shown in Figure 4A, after incubation with different concentrations of AgNPs (0.5 $\mu\text{g/mL}$, 1 $\mu\text{g/mL}$, and 2 $\mu\text{g/mL}$) for 4 h, the survival rates of PMNs, measured using the CCK-8 assay, were no statistical difference between them, while the rate in 4 $\mu\text{g/mL}$ was significantly decreased, indicating that PMNs showed acceptable biocompatibility when the AgNPs concentration was less than or equal to 2 $\mu\text{g/mL}$. This was further verified using the LDH release experiment shown in Figure 4B. Compared with the untreated group, the concentrations (0.5 $\mu\text{g/mL}$, 1 $\mu\text{g/mL}$, and 2 $\mu\text{g/mL}$) of AgNPs did not cause a significant increase in the release of LDH, while the concentration in 4 $\mu\text{g/mL}$ lead to a significant increase. Moreover, after incubation with AgNPs (0.5 $\mu\text{g/mL}$, 1 $\mu\text{g/mL}$, and 2 $\mu\text{g/mL}$), PMNs still maintained good morphological structure, as shown in Supplementary Figure S1.

Antimicrobial Evaluation of AgNPs and Isolated Human PMNs in vitro

First, the antimicrobial capability of AgNPs was evaluated in vitro using the spread-plate method. Briefly, different concentrations (0 $\mu\text{g/mL}$, 0.5 $\mu\text{g/mL}$, 1 $\mu\text{g/mL}$, and 2 $\mu\text{g/mL}$) of AgNPs were cocultured with 1 mL of 1×10^5 CFU/mL bacterial fluid for 4 h, and, as demonstrated in Figure 5A and B, the antibacterial ability of AgNPs increased as their concentration increased, showing a significant antibacterial effect at the concentration of 2 $\mu\text{g/mL}$. Furthermore, to estimate the effect of AgNPs on the antimicrobial ability of PMNs, after pretreatment with AgNPs for 2 h, PMNs

were isolated using centrifugation and incubated with bacteria. The antibacterial performance of PMNs, shown in Figure 5C and D, was inhibited by AgNPs pretreatment in a concentration-dependent manner. In

summary, AgNPs exhibited strong antibacterial activity, while PMNs also exhibited certain antimicrobial capabilities. However, when treated with AgNPs, the antimicrobial capability of PMNs was obviously inhibited.

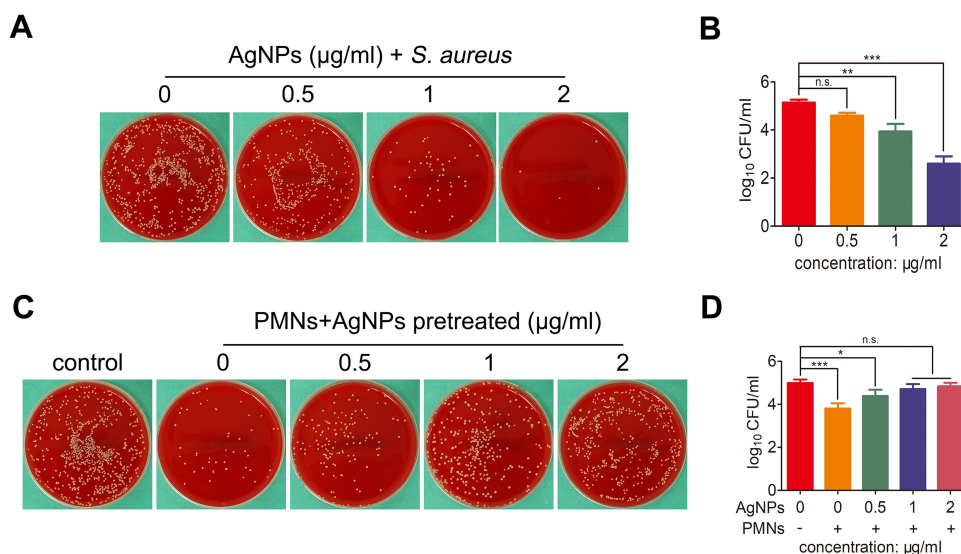

Figure 5 (A, B) Quantitative results obtained after treatment with different concentrations (0, 0.5, 1 and 2 µg/mL) of AgNPs. **(C, D)** Quantitative results obtained in human polymorphonuclear neutrophils (PMNs) treated with different AgNP concentrations (0, 0.5, 1 and 2 µg/mL). n.s. represents no statistical significance, * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$.

Antibacterial Evaluation of AgNPs in *S. aureus*-Infected Air Pouch Model

The antimicrobial efficacy of AgNPs *in vivo* was evaluated using the *S. aureus*-infected air pouch model. As shown in Figure 6A, compared with the control group, the images of fresh soft tissues in the AgNPs + *S. aureus* group and *S. aureus* group showed obvious hyperemia, swelling and purulent secretions, which proved that they had a serious infectious state. To investigate the bacterial burden *in vivo* in each group, pathological sections were obtained to assess the inflammatory and infectious state of soft tissue. As indicated in Figure 6B, hematoxylin and eosin (H&E) staining, used to detect the morphological changes of each group, revealed obvious acute inflammatory changes, massive neutrophil infiltration, and exudation in the *S. aureus* group. In contrast, a relatively mild degree of inflammation and less neutrophil infiltration were observed in the AgNPs + *S. aureus* group. Furthermore, the infectious state was confirmed using Giemsa staining (Figure 6C). A large number of bacteria were present in the *S. aureus* group, while a slightly smaller bacterial load was observed in the AgNPs + *S. aureus* group. To further verify the antibacterial performance of AgNPs *in vivo*, the bacterial burden was also evaluated using the spread-plate method, which confirmed the aforementioned results (Figure 7A and B), while the smaller bacterial counts in the AgNPs + *S. aureus* group compared with the *S. aureus* group did not reach statistical significance. Moreover, the inflammatory state of the infected air pouch

was explored by measuring the level of inflammatory factors in the extracted lavage fluid. As demonstrated in Figure 7C and D, the levels of TNF- α and IL-6 in the AgNPs + *S. aureus* group were significantly decreased compared with those in the *S. aureus* group in a dosage-dependent way.

The Antibacterial Potential Was Investigated Using an *ex vivo* Blood-AgNPs-Bacterial Interaction Model

After incubation for 90 min, the antibacterial performance of the blood in presence of AgNPs was slightly superior to that of the control group, but not significantly, as demonstrated using quantitative analysis (Figure 8A and B). This indicated that the presence of AgNPs might suppress the inherent antimicrobial activity of blood. The antibacterial ability of blood mainly comes from phagocytes, including innate immune cells. Therefore, to further understand the mechanism underlying the inhibited antimicrobial ability of blood, a phagocytosis assay was performed in an *ex vivo* model. As the time of blood-AgNP-bacteria incubation increased, the number of bacteria phagocytized by PMNs gradually increased (Figure 8C). However, compared with the group co-cultured with bacteria alone, the phagocytic capability of PMNs began to decrease in the groups incubated with AgNPs for 15 min, and this decrease in phagocytosis was inversely related to the concentrations of AgNPs. Furthermore, these outcomes were also verified using quantitative phagocytosis rate analysis

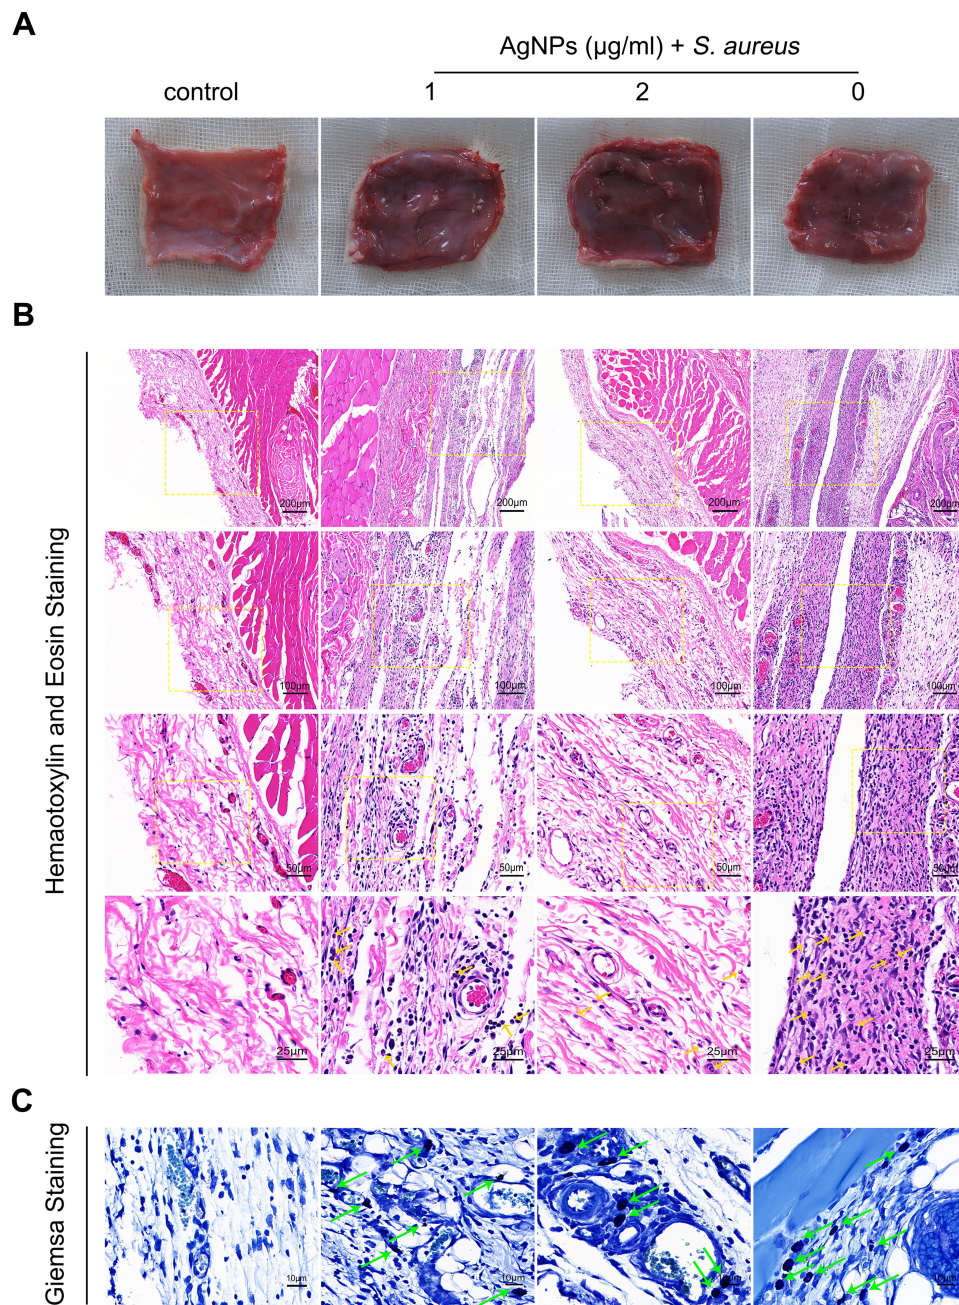

Figure 6 Histological evaluation of soft tissue of Sprague-Dawley (SD) rats at 24 h after the establishment of the air pouch model. **(A)** Representative photographs of fresh soft tissues. **(B)** Typical hematoxylin and eosin staining of soft tissues; the magnification increases sequentially from up to down. Yellow arrows in the images indicate polymorphonuclear neutrophil (PMNs). **(C)** Typical Giemsa staining of soft tissue es. Scale bar = 10 μm . Green arrows in the images indicate *Staphylococcus aureus*.

(Figure 8D). The mean phagocytosis rates at 15 min of incubation in the groups that received the AgNPs doses of 0, 0.5, 1 and 2 $\mu\text{g/mL}$, were 26.2%, 23.4%, 18.6% and 14.1%, respectively. At 30 min, the corresponding rates were 48.6%, 40.5%, 28.0% and 20.6%, at 60 min, 72.2%, 51.9%, 37.0% and 26.8%, and at 90 min, 78.1%, 57.6%, 43.2% and 31.8%. From a statistical point of view, the

S. aureus-induced group was significantly different from the AgNPs groups during incubation for 15–90 min, and the difference became more obvious as the co-culture time increased. Considering the AgNP groups, with the increase in interaction time, the higher the concentration of AgNPs, the stronger the inhibition of phagocytosis ability of PMNs.

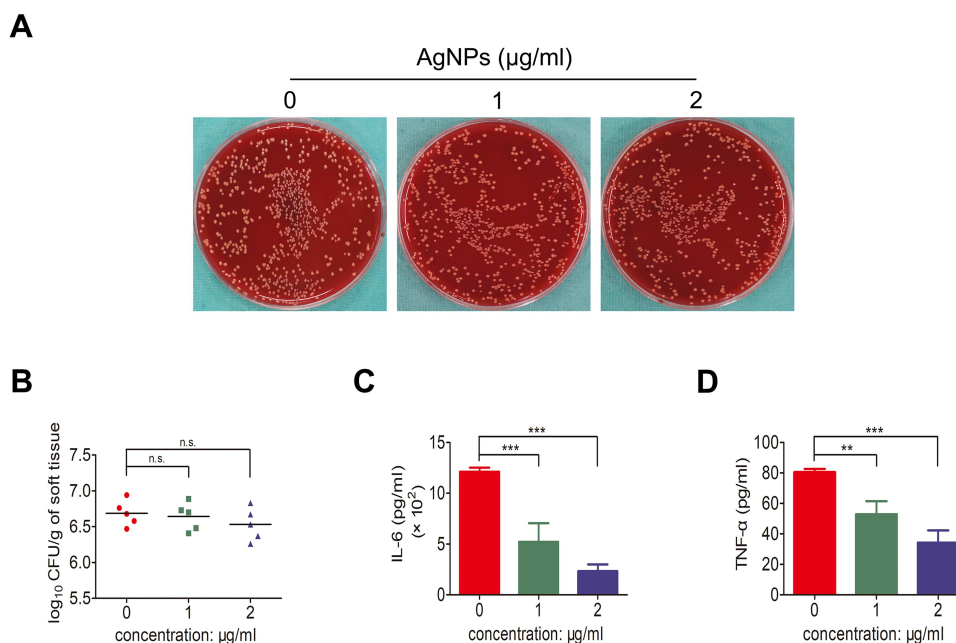

Figure 7 The antimicrobial efficacy of silver nanoparticles (AgNPs) in vivo in *Staphylococcus aureus*-infected air pouch. **(A, B)** quantitative results obtained after treatment with different concentrations (0, 1 and 2 µg/mL) of AgNPs and bacteria in vivo. **(C, D)** Cytokine levels (IL-6 and TNF-α) in lavage fluid extracted from Sprague-Dawley (SD) rats treated with different concentrations (0, 1 and 2 µg/mL) of AgNPs and bacteria. n.s. represents no statistical significance, **p < 0.01, ***p < 0.001.

PMN Lysis in Each Group

Next, the degree of PMN lysis was further investigated. As shown in Figure 8E, the mean PMN lysis rates were 26.9%, 36.0%, 35.4%, and 36.3%, when the concentration of AgNPs was 0, 0.5, 1, and 2 µg/mL, respectively. Although the presence of AgNPs in the concentrations used in this experiment slightly increased the PMN lysis rate compared with that of the *S. aureus* group, there was no statistical difference between them.

Inhibition of PMNs ROS and Superoxide Production

To explore the mechanism of the AgNPs-induced reduction of the antibacterial ability of PMNs, the production of ROS and superoxide by PMNs was evaluated and the results are shown in Figure 9A–C. The fluorescent images of ROS demonstrated that the AgNPs themselves did not have a significant effect on the level of ROS production by PMNs compared with the level in the control. On the contrary, after incubation with bacteria, ROS production by PMNs significantly increased, indicating that *S. aureus* promoted ROS production of PMNs. While cocultured with PMN and bacteria, AgNPs suppressed *S. aureus*-

induced ROS generation (Figure 9A). Furthermore, the fluorescence detected using a fluorescence microplate reader also indicated that AgNPs inhibited ROS production of PMNs, which were induced by *S. aureus* (Figure 9B). Subsequently, the results of superoxide production in each group were examined and, compared with those of the *S. aureus*-induced group, the superoxide production of PMNs treated with AgNPs and *S. aureus* was significantly decreased (Figure 9C). Generally, as mentioned above, PMNs ROS and superoxide production were obviously inhibited in the presence of AgNPs, and this inhibition was even more severe when higher concentrations of AgNPs were used.

The Migration Ability of Human PMNs Was Suppressed by AgNPs

Furthermore, the migration behavior of human PMNs was explored using a transwell experiment. As shown in Figure 10A and B, the number of PMNs migrating across the transwell membrane was decreased in a dosage-dependent manner in the AgNPs groups compared with the control group. Hence, the capability of PMNs to migrate to the infected site was gradually suppressed by AgNPs as their concentration increased.

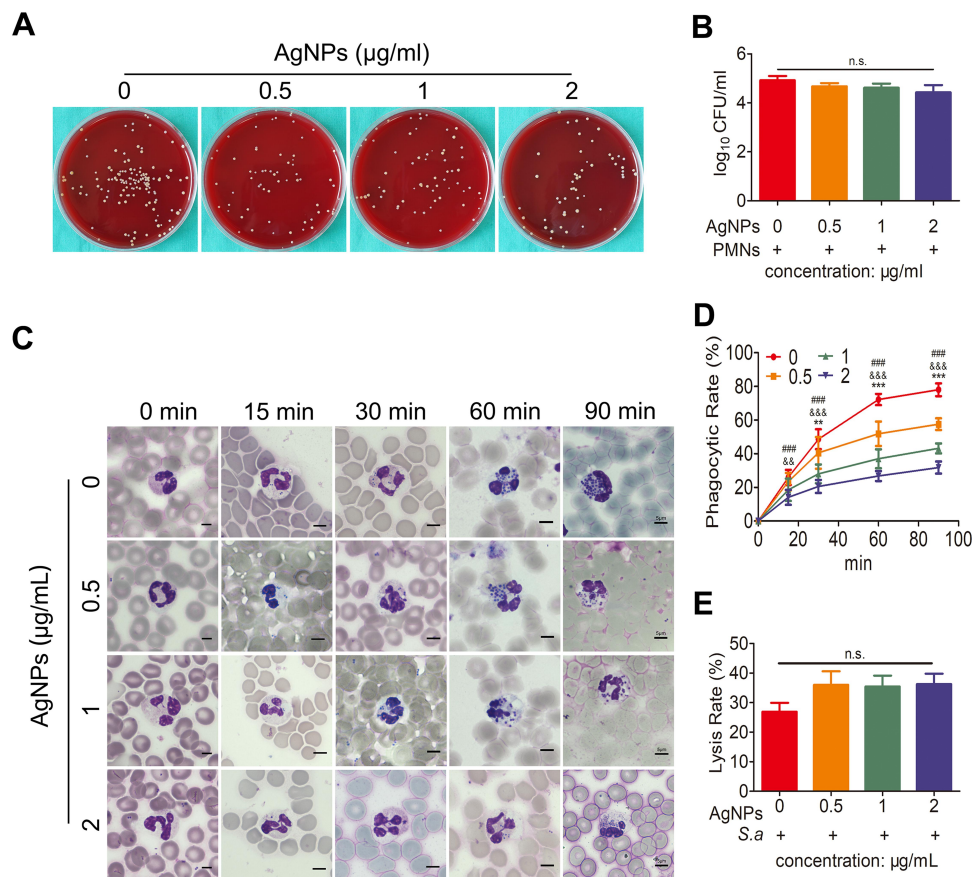

Figure 8 The antibacterial potential of silver nanoparticles (AgNPs) was investigated using an ex vivo blood-AgNP-bacterial interaction model. **(A, B)** Quantitative evaluation of the antibacterial efficacy against *Staphylococcus aureus* (*S. aureus*) following treatment with different concentrations (0, 0.5, 1 and 2 µg/mL) of AgNPs and *S. aureus* in a blood-AgNPs-bacteria system at 90 min. **(C)** Representative images of the blood-AgNPs-bacteria co-culture. AgNPs Inhibited the Production of Pro-Inflammatory Factors, RNA Expression by PMNs

The effects of AgNPs on PMNs pro-inflammatory cytokine secretion and the cytokine mRNA expression levels were further investigated, as demonstrated in Figure 10C–H. After the bacteria-PMNs-AgNPs system was incubated for 4 h, IL-1 β , IL-6, and MCP-1 were significantly lower in the AgNPs + *S. aureus* group than in the *S. aureus* group, especially in the high AgNP concentration group (Figure 10C–E). This trend was also confirmed on the mRNA level using RT-PCR (Figure 10F–H). These results indicated that in the presence of AgNPs, PMNs' ability to promote inflammation was severely limited.

Discussion

Neutrophils have long been considered to be extremely important in resisting the invasion of pathogenic microorganisms during the early stage of host infection.^{15,32} Since orthopedic biomaterials are developed as an anti-infective therapy, the optimization of these biomaterials is more focused on the improvement of their own antibacterial properties. Although neutrophils are also important in this process, few materials have been explored for their influence on the antimicrobial activity of neutrophils.^{21,22} As a result, biomaterials exhibiting good antibacterial activity in vitro may show a weakened or even lost antibacterial activity in vivo.³³ The purpose of this study was to explore the effects of AgNPs, which have excellent antibacterial properties, on the antimicrobial efficacy of

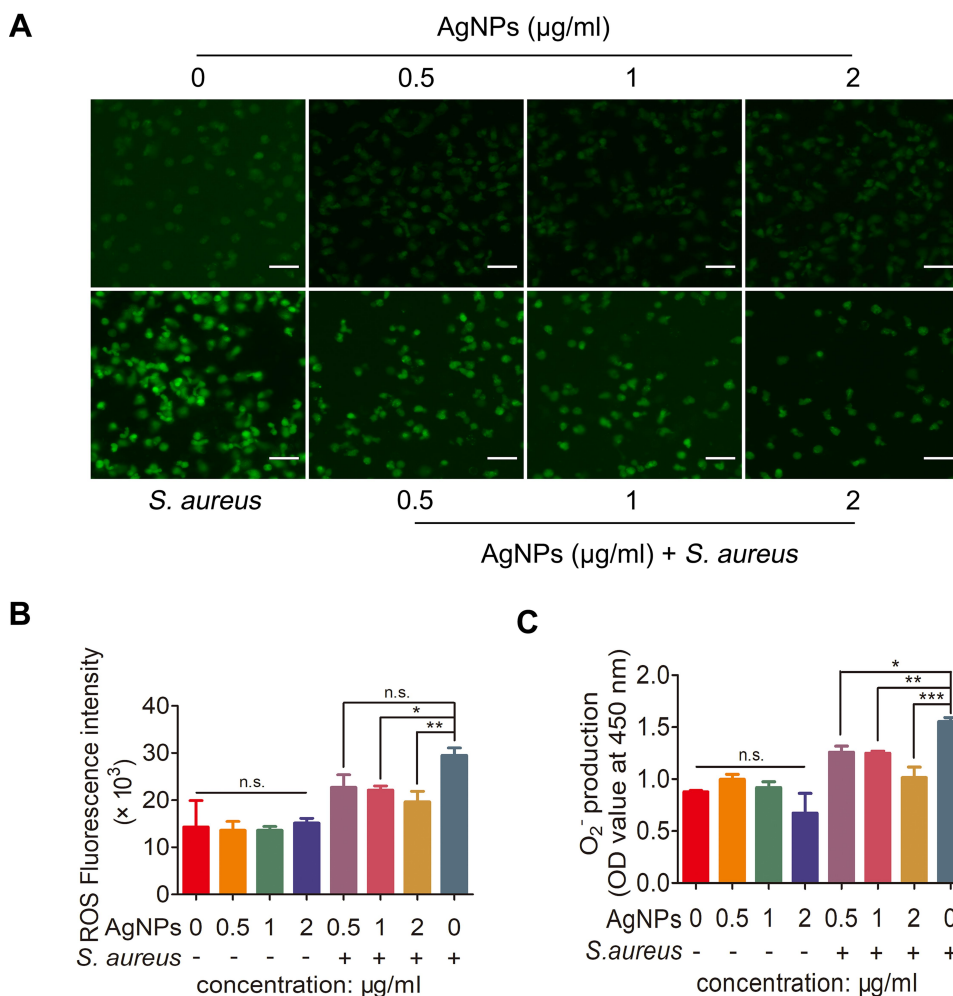

Figure 9 Inhibition of polymorphonuclear neutrophil (PMN) reactive oxygen species (ROS) and superoxide production. **(A)** Representative fluorescent pictures of ROS production (DCFH-DA) by human PMNs when exposed to different concentrations (0, 0.5, 1 and 2 $\mu\text{g/ml}$) of AgNPs with or without *Staphylococcus aureus* (*S. aureus*) at 2 h. Scale bar = 50 μm . **(B)** Fluorescence quantification measurement of DCF signals in human PMNs treated with different concentrations (0, 0.5, 1 and 2 $\mu\text{g/ml}$) of AgNPs with or without *S. aureus* using a fluorescence microplate reader. **(C)** Quantification of superoxide production of human PMNs. n.s. represents no statistical significance, * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$.

neutrophils in vivo and in vitro, and to further investigate the underlying mechanism.

The antibacterial efficacy of AgNPs was first evaluated in vitro. At the selected concentration, AgNPs exerted a good antibacterial effect. Previous studies have reported that AgNPs may have a negative impact on host cells and tissues at the concentration necessary to exhibit antibacterial effects.^{34–36} To this end, the biosafety of AgNPs was further investigated at the chosen antimicrobial dosages. In this study, good cell biocompatibility was observed in vitro. Therefore, the concentration of AgNPs selected in this study creates a balance ideal between antimicrobial activity and biocompatibility. In addition, an infected air pouch model was established, which can be used to study the

biomaterials, evaluate the tissue response to these materials under acute inflammation, and observe the antibacterial phenomenon of AgNPs in vivo.³⁷ However, when Giemsa staining and dilution spread-plate method were used to investigate the in vivo antibacterial effect of AgNPs, the results were opposite to those obtained in vitro; that is, AgNPs did not exert their proper antibacterial activity.

Considering that AgNPs were not the only factor to exert antibacterial ability in vivo, and that the innate immune system of the host plays the most vital role in resisting bacterial invasion,^{38,39} the level of inflammation in the body was evaluated using lavage fluid and H&E staining. The results showed that the presence of AgNPs decreased the inflammation level in the lavage fluid and

the number of neutrophils around the infected soft tissue, which further proved that the changes in the results in vivo may be closely related to the suppression of the innate immune system.

It is well known that the in vivo environment is far more complex than in vitro models. When medical biomaterials are implanted into the human body, surgical operation will inevitably cause local tissue injury and bleeding, therefore there will be blood on the surface of the implant. At this point, blood will act as a medium in which biomaterials, bacteria and neutrophils can interact with each other. In order to better understand the underlying antibacterial and inflammatory phenomena in vivo, a blood-AgNP-bacteria

microenvironment was constructed to explore the reasons for the difference in the in vivo and in vitro antibacterial effects of AgNPs. The antibacterial results of incubation with human blood for 90 min demonstrated that the antimicrobial efficacy in the AgNPs group was not significantly improved (Figure 8A), contrary to the results observed in vitro (Figure 5A), and provided an indication of the effects in vivo. Neutrophils, a type of immune cells accounting for 60–70% of circulating white blood cells, are an indispensable component of innate immunity.^{38,40} Therefore, the presence of blood antibacterial ability may be due to the change in the bactericidal ability of neutrophils. Phagocytosis is the most crucial antibacterial weapon

of neutrophils, which largely determines the host's ability to resist pathogen infection.^{41,42} The results of Wright–Giemsa staining of blood smears confirmed that AgNPs significantly inhibited the phagocytosis efficacy of neutrophils.

When neutrophils encounter and phagocytize pathogens, phagocytosis triggers many processes in neutrophils, one of which is to transfer electrons to oxygen molecules through NADPH oxidase in the respiratory chain, resulting in the production of superoxide anions.⁴³ Superoxide anions are the initiating switch, which will further lead to the production of ROS.⁴⁴ This process is called a respiratory burst. Both superoxide anion and ROS production is mediated by NOX2,^{45,46} which exerts important effects on the pathogen killing process.^{47–49} As shown in Figure 9A–C, AgNPs alone did not cause significant changes in the levels of ROS and superoxide in neutrophils, which was consistent with the results reported by Poirier et al.¹¹ However, AgNPs suppressed the production of ROS and superoxide by neutrophils, when incubated with bacteria. Since NOX2 is the intermediary in the production of ROS and superoxide, we speculated that AgNPs might inhibit the activity of NOX2, thus reducing the ability of neutrophils to produce both in presence of bacteria. PI3K and AKT-1 are intracellular signal molecules closely related to ROS production when neutrophils are stimulated, which can produce high intensity of ROS through the activation of NADPH oxidase.^{50–52} Further research needs to be conducted to explore in depth how AgNPs affect the antibacterial performance of innate immunity and reveal the underlying molecular mechanisms.

This study mainly explored the effect of AgNPs on ROS production and phagocytosis of PMNs in the antibacterial process and its possible mechanism. It is worth noting that in addition to the bactericidal effect of PMNs through phagocytosis and ROS production, degranulation and NETs are also the other two main antimicrobial pathways of PMNs.^{16,17} Furthermore, when blood comes into contact with biomaterials, the complement system will be activated through the classical pathway, which can further activate the surrounding immune cells by forming membrane attack complex to resist pathogenic bacteria.⁵³ Except for neutrophils, there are many other innate immune cells (including macrophages) that also play a vital role in protecting human body from bacterial invasion. In addition, it is worth mentioning that the human peripheral blood contains heterogeneous populations of neutrophils at different mature and active stages.⁵⁴ Fraser

et al²⁸ reported that AgNPs could trigger the emergence of CD16^{bright}/CD62L^{dim} neutrophils, which exhibit lower ability of phagocytosis and ROS production compared with classical pro-inflammatory neutrophils.⁵⁵ The factors mentioned above may be affected to varying degrees in presence of AgNPs, and may also explain the inconsistency between in vivo and in vitro results observed in this study. In this study, we only studied one kind of AgNPs, however AgNPs have different biological characteristics according to their size⁵⁶ and shape.⁵⁷ Liz et al²⁹ reported that 15 nm AgNPs induced the atypical death of neutrophils which was mainly dependent on ROS, caspase-1 and caspase-4 levels. While, in our study, there was no significant increase in the death of neutrophils and the production of ROS within the working concentration range of AgNPs, which may be attributed to the fact that the size of AgNPs and working concentration of silver nanoparticles are still within cell safe range.

Furthermore, Haase et al⁵⁸ recently reported the effects of silver (Ag⁺) released by AgNPs and AgNPs on innate immune system cells, and the results indicated that the Ag⁺ released from AgNPs as the component responsible for immunomodulatory activity of AgNPs on primary human leukocytes and macrophages. While AgNPs was used as a whole to explore the immunomodulatory effect only to PMNs against microbial invasion, emphasizing the overall effect in our study. We did not further distinguish between the immunomodulatory effects of Ag⁺ released by AgNPs and AgNPs on PMNs, which will have a certain guiding significance for the future research.

Conclusion

We showed that AgNPs have excellent antibacterial properties in vitro; however, their antibacterial activity was greatly weakened when applied in vivo. Furthermore, a decrease in the expression of pro-inflammatory factors and the number of neutrophils recruited to inflammatory sites was observed. Moreover, the results of the ex vivo model we established to simulate the in vivo environment, demonstrated that the presence of AgNPs inhibited the antibacterial ability of the innate immune system, which was further verified by the reduced ability of PMNs to phagocytize bacteria. The results of co-culture of human neutrophils with bacteria and AgNPs indicated that AgNPs significantly inhibited the capability of neutrophils to produce ROS and superoxide as well as the migratory ability of PMNs. AgNPs are among the inorganic nanomaterials with high antibacterial properties. Studying the effects of

AgNPs on the innate immune system's response to invasion by foreign microorganisms may give a cue, in the development or optimization of antibacterial biomaterials, actively mobilizing or even improving the antibacterial efficacy of the innate immune system might lead to great therapeutic effects.

Supporting Information

Fluorescence images of human PMNs co-cultured with different concentrations (0.5, 1 and 2 $\mu\text{g/mL}$) of AgNPs for 4 h (PDF).
