**Abstract:** Dual-modality imaging combines the complementary advantages of different modalities, and offers the prospect of improved preclinical research. The combination of fluorescence imaging and magnetic resonance imaging (MRI) provides cross-validated information and direct comparison between these modalities. Here, we report on the application of a novel tumor-targeted, dual-labeled nanoparticle (NP), utilizing iron oxide as the MRI contrast agent and near infrared (NIR) dye Cy5.5 as the fluorescent agent. Results of in vitro experiments verified the specificity of the NP to tumor cells. In vivo tumor targeting and uptake of the NPs in a mouse model were visualized by fluorescence and MR imaging collected at different time points. Quantitative analysis was carried out to evaluate the efficacy of MRI contrast enhancement. Furthermore, tomographic images were also acquired using both imaging modalities and cross-validated information of tumor location and size between these two modalities was revealed. The results demonstrate that the use of dual-labeled NPs can facilitate the dual-modal detection of tumors, information cross-validation, and direct comparison by combining fluorescence molecular tomography (FMT) and MRI.

**Keywords:** dual-modality, fluorescence molecular tomography (FMT), magnetic resonance imaging (MRI), nanoparticle

## Introduction

Dual-modality imaging is a powerful method that combines the complementary advantages of different imaging modalities.<sup>1</sup> The fusion of functional/molecular and anatomical modalities, including positron emission tomography/computed tomography (PET/CT), single-photon emission CT (SPECT)/CT, PET/magnetic resonance imaging (MRI), etc, has gained worldwide attention as providing more reliable and accurate disease detection.<sup>2</sup> As a non-radiative functional imaging modality, fluorescence imaging is emerging as an important method and plays a significant role in tumor detection<sup>3</sup> and drug development.<sup>4</sup> Fluorescence imaging has several advantages over other modalities, such as high sensitivity and specificity, operational simplicity, safety and cost effectiveness.<sup>5</sup> Lately, combined with the development of versatile fluorescent probes, especially the near-infrared fluorescent (NIRF) probes, fluorescence molecular tomography (FMT) is becoming a promising tool to noninvasively resolve three-dimensional (3D) spatial distribution of fluorescence probes associated with molecular and cellular functions.<sup>6</sup> On the other hand, MRI provides high spatial resolution with outstanding contrast features in soft tissues,<sup>7</sup> 3D anatomic details throughout the body, and has been widely used in clinical oncology imaging.<sup>8</sup> Novel contrast agents that modulate T<sub>1</sub> and T<sub>2</sub> relaxation have also rendered MRI a tool for visualizing cellular

and subcellular events.<sup>9</sup> In light of these recent advances, the combination of fluorescence imaging and MRI is particularly attractive, and has been utilized for tumor detection,<sup>8</sup> imaging of myocardium,<sup>10</sup> protein expression,<sup>11</sup> etc.

Recently, nanoparticle (NP)-based imaging has attracted considerable attention. NPs have been widely used as the imaging contrast agent for their potential for earlier diagnosis,<sup>12</sup> greater biocompatibility, and reduced toxicity.<sup>13</sup> To achieve enhanced specificity and sensitivity, tumor-targeted NPs have been developed, and their feasibility in tumor-targeted imaging has been demonstrated *in vivo*.<sup>8,14</sup> Using monoclonal antibodies targeted against the receptor, epidermal growth factor receptor (EGFR) is under intense investigation, both as a prognostic marker and for therapy by means of optical imaging<sup>15</sup> and MRI.<sup>16</sup> The EGFR signaling pathway plays an important role in the regulation of cell proliferation, etc.<sup>17</sup> EGFR is overexpressed in many solid tumors, including cancers of breast, brain, colon, etc.,<sup>18</sup> and the different levels of expression between normal cells and tumor cells make EGFR a potential marker for *in vivo* receptor-targeted molecular imaging.<sup>15</sup> Furthermore, dual-labeled NPs have made a significant contribution to promoting the development of dual-modality imaging. By integrating several imaging agents with different properties, dual-labeled NPs can be used to evaluate the same molecular target with multiple imaging modalities,<sup>19</sup> quantitatively assess tumor-targeting efficacy,<sup>20</sup> and detect tumors at early stages with high accuracy.<sup>21</sup>

In order to facilitate the cross-validation and direct comparison between the tomographic images acquired by FMT and MRI, an EGFR-targeted, dual-labeled magnetic-fluorescent NP was synthesized. Fluorescence imaging and MRI were used to observe the dual-labeled NP distribution in a mouse mammary tumor model *in vivo*. A series of fluorescence images and MRI images were collected at different time points to observe tumor targeting and uptake of the NPs, and quantitative analysis was carried out. Tomographic images acquired from fluorescence imaging and MRI were also shown. The results from both imaging modalities showed high correspondence with each other. Finally, histological analysis was conducted to further confirm the imaging results.

## Materials and methods

### Materials

Iron(III) acetylacetonate (Fe(acac)<sub>3</sub>), oleylamine, 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC), N-hydroxysulfosuccinimide sodium salt (sulfo-NHS), fetal bovine serum, Penicillin-Streptomycin were purchased from

Sigma-Aldrich (St Louis, MO, USA). Diphenyl ether was purchased from Sinopharm Chemical Reagent Beijing, Co, Ltd (Beijing, People's Republic of China). The anti-EGFR monoclonal antibody (mAb) was purchased from Boehringer Ingelheim Pharma GmbH and Co. KG. (Ingelheim, Germany), and Cy5.5-NHS ester was purchased from GE Healthcare Life Science (Buckinghamshire, UK).

### Preparation of tumor-targeted dual-labeled NP

To achieve optimal dual-modality imaging contrast, paramagnetic iron oxide (IO) NPs conjugated with NIRF dye-labeled mAbs were synthesized. IO NPs were prepared as previously described.<sup>22–24</sup> Typically, 2.1 g of Fe(acac)<sub>3</sub>, 7.9 mL of oleylamine, and 24 g of HOOC-PEG-COOH (12 mmol, Mn=2,000) were dissolved in 100 mL of diphenyl ether solution. After being purged with nitrogen, the reaction mixture was quickly heated and kept refluxing for 0.5 hours. After the reaction mixture was cooled to room temperature, ether was used to precipitate the resultant Fe<sub>3</sub>O<sub>4</sub> nanocrystals out of it. The precipitate was then re-dissolved in ethanol followed by addition of ether as precipitant. This purifying procedure was repeated for three cycles. The polyethylene glycol (PEG)-coated Fe<sub>3</sub>O<sub>4</sub> nanocrystals finally obtained were dissolved in phosphate-buffered saline (PBS; Sigma, St Louis, MO, USA). Anti-EGFR mAbs were selected as the ligand for EGFR to achieve targeted delivery of the NP to the mammary tumor. The anti-EGFR mAb was dialyzed against 1 L of 0.15 M sodium chloride for 4 hours at room temperature, and was dialyzed again overnight using a fresh liter of 0.15 M sodium chloride at 4°C. A 10 mg/mL solution of Cy5.5-NHS ester in dimethyl sulfoxide (DMSO) was then added gradually to the antibody solution while stirring in the dark. To separate the free dye, the mixture was dialyzed against 1 L of 0.15 M sodium chloride for 4 hours at room temperature. This dialysis was repeated using a fresh liter of 0.15 M sodium chloride overnight at 4°C. Finally, the labeled antibody solution was filtered through a 0.22 μm syringe filter. Cy5.5 dye-labeled anti-EGFR mAbs were conjugated to the surface of IO NPs via the classical EDC/sulfo-NHS method.<sup>23,24</sup> Typically, EDC (2.50 μmol) and sulfo-NHS (6.25 μmol) were dissolved in 950 μL of a 0.01 M PBS solution containing 2.0 mg of Fe<sub>3</sub>O<sub>4</sub> nanocrystals. After approximately 15 minutes, 50 μL of a 0.01 M PBS solution containing 1 mg of Cy5.5 labeled anti-EGFR antibody was introduced. The reaction was run overnight at 4°C. The resultant conjugates were collected at 13,000 rpm to remove the impurities and unreacted Cy5.5

labeled anti-EGFR antibody molecules and then re-dissolved in PBS (1 mL) and kept at 4°C.

Transmission electron microscopy (TEM) of IO-anti-EGFR-Cy5.5 was used to estimate the diameter of the particle. In order to determine the concentration of iron in the probe, O-phenanthroline spectrophotometry was carried out. Firstly, the standard solution of iron was prepared and then diluted to different known concentrations. Then a 0.10% solution of O-phenanthroline and a 10% solution of hydroxylamine hydrochloride were added to the standard solutions of serial concentration. The standard curve was created by measuring the percent transmittance of the mixed solutions by using the spectrophotometer (Cary 50 UV-vis, Angilent Technologies, CA, USA). Third, the probe solution was processed as above, and the percent transmittance was also measured. Thus, the concentration of the probe could be determined according to the standard curve. The optical properties of anti-EGFR-Cy5.5 and IO-anti-EGFR-Cy5.5 were also investigated.

## Cell lines

Human breast adenocarcinoma cell lines MDA-MB-231 (EGFR-positive) and MDA-MB-453 (EGFR-negative) were purchased from National Platform of Experimental Cell Resources for Sci-Tech (Beijing, People's Republic of China), and were maintained at 37°C in a humidified atmosphere containing 5% CO<sub>2</sub> in RPMI 1640, supplemented with 10% fetal bovine serum and 1% Penicillin- Streptomycin.

## In vitro binding studies

Both cell lines cultured in a 35 mm confocal dish (Corning, New York City, NY, USA) were incubated with IO-anti-EGFR-Cy5.5 of the same concentration (containing 135 mg Fe) at 37°C for 1 hour. After washing with PBS three times, cells were fixed with 4% paraformaldehyde (Beijing Chemical Works, Beijing, People's Republic of China) and cell nuclei were then stained with Hoechst 33342 (Sigma-Aldrich, St Louis, MO, USA) by incubating the cells with 10 mg/mL Hoechst 33342 solution for 15 minutes at 37°C. Cells were then washed again three times, and the dishes were mounted for microscopic examination using a confocal microscope (A1R MP, Nikon, Tokyo, Japan).

## Mouse mammary tumor model

Animal experiments were approved by the Institutional Animal Care and Use Committee of Tsinghua University, Beijing.  $5 \times 10^6$  MDA-MB-231 cells in 0.15 mL PBS were injected

subcutaneously into the upper right mammary fat pad of five 5-week-old female BALB/c-nude mice. When the average diameter of tumors reached ~6 mm, the mice were imaged.

## In vivo fluorescent imaging

All fluorescence imaging experiments were performed on a home-made fluorescence imaging system. A 300 W Xenon lamp (Asahi Spectra, Torrance, CA, USA) was employed as the excitation source. Both reflectance imaging and tomographic imaging were carried out in the experiments. A collimation lens was used in reflectance imaging to generate approximately uniform epi-illumination; in the tomographic imaging, a fiber was attached to the lamp to generate a light spot focused onto the surface of the mouse. A 512 × 512 pixel, electron-multiplying CCD (EMCCD) camera (iXon DU-897, Andor, Belfast, Northern Ireland, UK) was cooled to -70°C and used to detect the fluorescence signals. A 35 mm f/1.6 lens (C3514-M, Pentax, Tokyo, Japan) was coupled to the EMCCD camera. The EMCCD camera and the excitation light source were vertically rotated, while the mouse was horizontally fixed on an animal holder (Figure 1A and B). The same mouse positions were carefully maintained, and identical imaging parameters were used, throughout the experiments. Fluorescent images were acquired with a 670±5 excitation filter and a Cy5.5 emission filter (695–770 nm, Caliper Life Sciences, Hopkinton, MA, USA). The mice were anesthetized with an isoflurane-oxygen gas mixture during the imaging process.

**Figure 1** The animal holder.

**Notes:** (A) Components of the holder: a plastic tube and two carbon sticks to hold the mouse. Fixation mode of the holder in the homemade fluorescence molecular tomography system (B) and in the customized rodent coil (C).

A total of 75  $\mu\text{L}$  of IO-anti-EGFR-Cy5.5 NPs (1.14 nM Fe per kg of mouse body weight) was administered via the tail vein before imaging. Fluorescent reflectance images were collected for each mouse ( $n=5$ ) at four different time points to monitor the changes in fluorescence intensity in the tumor over time; the exposure time of CCD was 4 seconds. Fluorescent images for FMT were collected 12 hours post-injection, utilizing 36 projections with an angular increment of  $10^\circ$ . The total scan time for FMT was about 10 minutes. In fluorescence reconstruction, only the tumor region was reconstructed; the resulting reconstruction had the dimensions  $31 \times 31 \times 18$  with a pixel size of  $1 \times 1 \times 1 \text{ mm}^3$ . The surface of the mouse was first extracted from the white light images by an optimal radon transform.<sup>25</sup> A 3D solid model was constructed using this information, and then discretized into finite elements in order to calculate the light transportation using the finite elements method (FEM).<sup>26,27</sup> The weight matrix was subsequently established by mapping the excitation light and the fluorescent images of each angle into the corresponding position of the finite element meshes. Finally, the algebraic reconstruction technique (ART) method was adopted to reconstruct the 3D dual-labeled NP distribution.

### In vivo MRI

MRI experiments were performed on a 3T MRI scanner (Achieva 3.0T TX; Philips Healthcare, Best, The Netherlands) using a customized rodent coil (Figure 1C). During the experiments, mice were fixed on the same holder as in the fluorescent imaging process, and were anesthetized with intraperitoneal injection of avertin (350 mg/kg). MR images of each mouse ( $n=5$ ) were collected before and 12 hours after the NP injection. The imaging sequences included  $T_1$ -weighted turbo field echo method with a repetition time (TR) of 7.8 ms, an echo time (TE) of 3.3 ms,  $T_2$ -weighted turbo spin echo method with a TR of 2,900 ms, and a TE of 214.1 ms. Multi-echo spin echo with six different TE values ranging from 15 ms to 90 ms were also used to obtain  $T_2$  maps of the whole mouse. Multi-echo  $T_2$  images of slices were used for calculating  $T_2$  maps using a commercial software (Volume View, Philips Healthcare, Best, The Netherlands). To estimate the contrast enhancement of NPs in the tumor at different time points, MRI signal changes were measured before and 12 hours after the injection. Using the MRI signal level of muscle tissue as a baseline, relative signal intensity was determined as follows:

$$\text{Relative signal intensity} = \frac{T_2 \text{ intensity}_{\text{tumor}}}{T_2 \text{ intensity}_{\text{muscle}}} \quad (1)$$

### Statistical analysis

Quantitative data were expressed as mean  $\pm$  standard deviation (SD). The paired Student's *t*-test was used to compare data in the regions of interest (ROIs) drawn around the tumor on the  $T_2$ -weighted images and  $T_2$  maps from the same animal before and after injection to evaluate the efficacy of contrast enhancement.  $P < 0.05$  was considered statistically significant.

### Histological analysis

After the mice were sacrificed, tumor tissues were collected and embedded optimal cutting temperature compound (OCT) (Sakura Fine-tek, Torrance, CA, USA), and  $10 \mu\text{m}$ -thick sections were cut. Frozen tissue sections were incubated with Prussian blue staining solution to confirm the presence of IO NPs in the tissue sections. The slides were examined under bright field microscopy (Eclipse 90i, Nikon, Tokyo, Japan) after counterstaining with eosin (Leagene Biotech, Beijing, People's Republic of China).

## Results

### Characterization of IO-anti-EGFR-Cy5.5

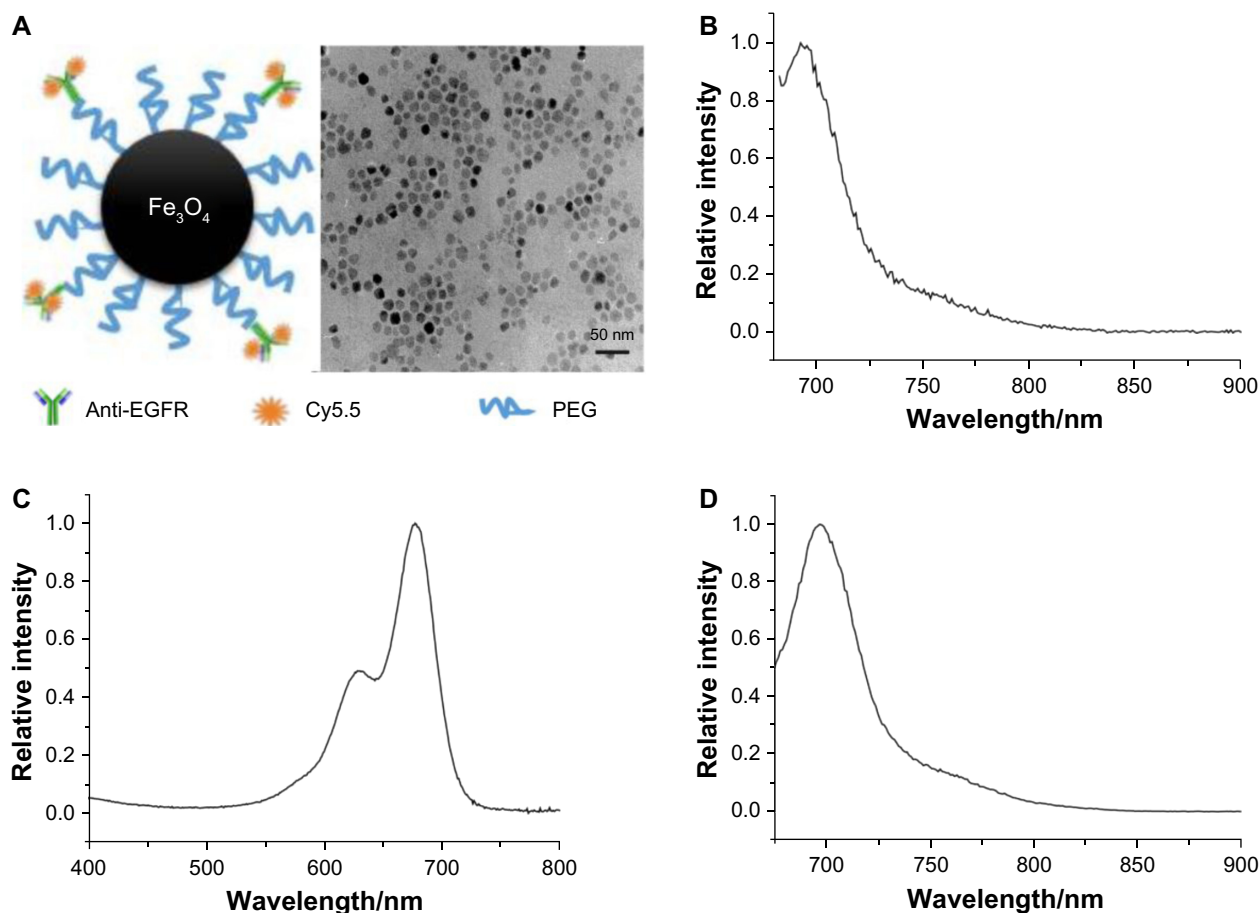

The components of IO-anti-EGFR-Cy5.5 are schematically depicted in Figure 2A. The NP consists of an IO core coated with PEG and Cy5.5-labeled mAbs (Figure 2A). According to the TEM images of the NPs (Figure 2A),  $\text{Fe}_3\text{O}_4$  magnetic NPs were approximately spherical, and the mean size was approximately 14 nm. The concentration of Fe in the probe was 1.7 mg/mL, determined by O-phenanthroline spectrophotometry.

The fluorescence emission spectrum of IO-anti-EGFR-Cy5.5 is shown in Figure 2B, while the fluorescence absorbance spectrum and emission spectrum of anti-EGFR-Cy5.5 are shown in Figure 2C and D, respectively. As shown in fluorescence spectra of anti-EGFR-Cy5.5, its absorbance peak is 670 nm, and its emission peak is  $\sim 700$  nm; filters of the corresponding wavelength are used in the following in vivo fluorescence imaging.

Furthermore, according to the product protocol of Cy5.5-NHS, the ratio of antibody to Cy5.5 is 1:2, calculated as follows:

$$\begin{aligned} D/P &= [\text{dye}]/[\text{antibody}] \\ &= [0.68 \times (A_{650})]/[A_{280} - (0.05 \times A_{650})] \quad (2) \end{aligned}$$

where  $A_{650}$  and  $A_{280}$  represent the absorbance of the Cy5.5-labeled anti-EGFR at the corresponding wavelengths (ie, 650 nm and 280 nm). The ratio of antibody to IO

**Figure 2** Characteristics of the IO-anti-EGFR-Cy5.5 nanoparticle.

**Notes:** (A) Schematic representation of the nanoparticle and the TEM image of IO-anti-EGFR-Cy5.5. (B) Normalized emission spectrum of IO-anti-EGFR-Cy5.5. (C and D) Normalized absorbance and emission spectra of anti-EGFR-Cy5.5.

**Abbreviations:** EGFR, epidermal growth factor receptor; IO, iron oxide; PEG, polyethylene glycol; TEM, transmission electron microscopy.

particle is 4:1. Thus, eight Cy5.5 molecules are labeled to each IO NP.

### Specificity of IO-anti-EGFR-Cy5.5 to cancer cells

In vitro binding studies were carried out to evaluate the specificity of the dual-labeled NP to EGFR-expressing tumor cells. MDA-MB-231 and MDA-MB-453 cells were incubated with IO-anti-EGFR-Cy5.5 under identical circumstances. Fluorescence images of MDA-MB-231 cells (Figure 3A) indicated that a strong fluorescence signal (red) was detected in the cells. In contrast, a negligible signal was detected in MDA-MB-453 cells (Figure 3B). The cell nuclei were counterstained with Hoechst 33342 (blue).

### In vivo fluorescence reflectance imaging

Representative fluorescence reflectance imaging results from one mouse are shown in Figure 4; the accumulation of the NPs in the tumor area is detected, as evidenced by the changes

in the fluorescent signals in serial NIR fluorescence images at four different time points. Meanwhile, strong fluorescent signals were also detected in the abdominal cavity, which was caused by the uptake of the NP by the liver and spleen.<sup>15</sup>

### In vivo FMT and MRI

To achieve the 3D distribution of the dual-labeled NP, in vivo tomographic imaging of the mammary xenograft mouse model was performed using both FMT and MRI.

As shown in Figure 5A and B, the tumor can be visualized with high contrast in both axial and coronal slices. Meanwhile, reductions of  $T_2$  signal and values in  $T_2$ -weighted images were observed in the area of the tumor 12 hours after the NP injection (Figure 5E–G), which suggests NP accumulation in tumors. Furthermore, signal changes in the tumor region are non-uniform, indicating the heterogeneous intratumoral distribution of the NPs. Using the MRI signal level of muscle tissue as a baseline, paired *t*-tests demonstrated that there was a significant change in relative magnetic signal intensity

**Figure 3** Specific binding of IO-anti-EGFR-Cy5.5 to targeted tumor cells line.

**Notes:** Strong fluorescence signals (Red) were found on the cell surface of MDA-MB-231 which overexpress EGFR, while there are no evident fluorescence signals on the cell surface of MDA-MB-453. Blue: Hoechst 33342 counterstaining.

**Abbreviations:** EGFR, epidermal growth factor receptor; IO, iron oxide.

( $P < 0.05$ ) 12 hours after the NP injection (Figure 6A). Similar results were obtained in the paired *t*-test for  $T_2$  values (Figure 6B), which further demonstrated the accumulation of the NP in the tumor. Tumor uptake of IO-anti-EGFR-Cy5.5 was confirmed by histology using Prussian blue staining. Cells with blue staining were found in tumor tissue sections

(Figure 6C). At the same time, uptake of the NP in the liver was also significant, as evidenced by a conspicuous signal decrease detected in the liver (Figure 5D and H) and in liver tissue slices (Figure 6D).

Furthermore, 3D FMT reconstruction reveals the distribution of the NPs in the tumor region 12 hours after the injection.

**Figure 4** Reflectance fluorescence images at four time points after the nanoparticle injection. Pixel values are reported as CCD counts, which is in proportion to fluorescence intensity.

**Note:** Red arrows indicate the tumor.

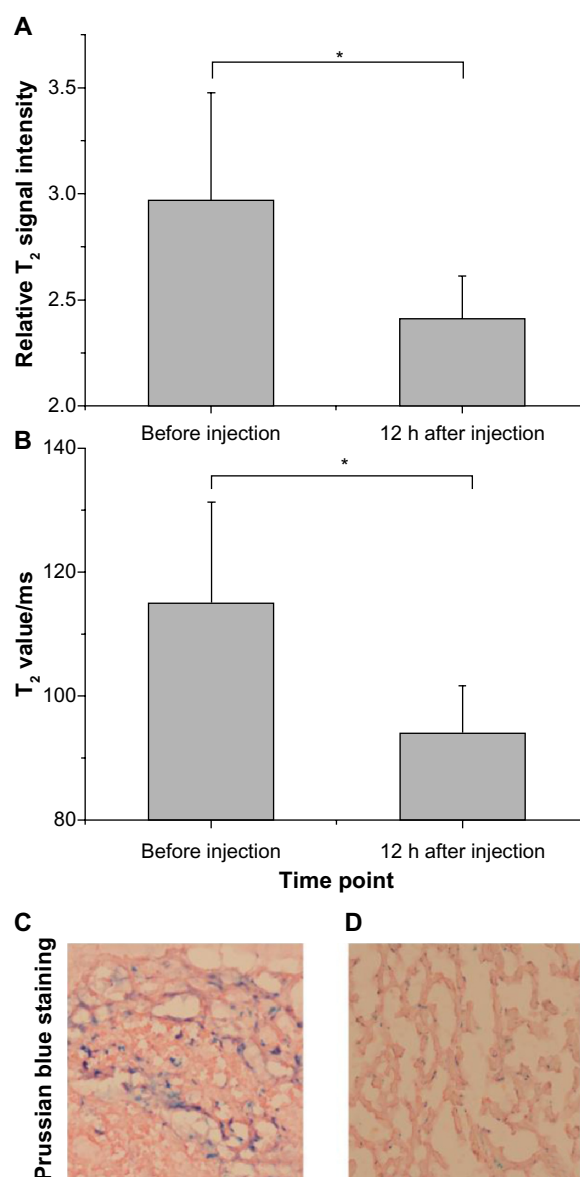

**Figure 5** In vivo MRI of MDA-MB-231 mammary tumor using IO-anti-EGFR-Cy5.5. **Notes:** (A, B, E, and F) Representative axial and coronal slices through the tumor before and 12 hours after the injection of the nanoparticle. Tumors (indicated by red circles) were visualized with high contrast. (C and G)  $T_2$  maps before and after the injection of the nanoparticle. (D and H) Axial slices through the liver showing significant  $T_2$  signal changes in the liver. **Abbreviations:** EGFR, epidermal growth factor receptor; IO, iron oxide; MRI, magnetic resonance imaging.

Figure 7 shows the axial MR images and the corresponding FMT images of the same mouse. As shown, NP distribution revealed in the fluorescence tomographic images corresponds well with that revealed in the MR images.

## Discussion

Fluorescence imaging, especially FMT, enables noninvasive detection and 3D reconstruction of specific molecular events, while MRI allows for imaging with high spatial resolution (0.5 mm herein) anatomic information. In this work, we acquired tomographic images of MRI and fluorescence

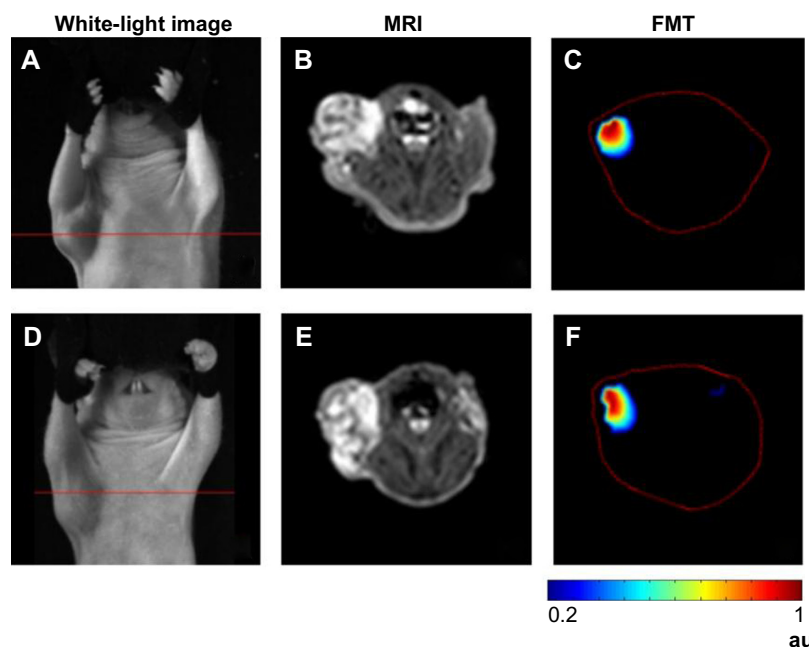

**Figure 6** Tracking changes of  $T_2$  intensity and  $T_2$  values before and after the nanoparticle injection.

**Notes:** Changes of the  $T_2$  intensity (A) and  $T_2$  value (B) of tumors before and after the nanoparticle injection. Columns, mean; error bars, standard deviation. \*indicates  $P < 0.05$ . imaging, which visualized the distribution of NIR dye-labeled, tumor-targeted NPs in vivo, and signal contrasts were detected and analyzed. As shown in the results, the new application, combining our homemade FMT system and the well-established MRI system, can provide cross-validated information and direct comparison between both modalities. The comparison and cross-validation may be further used for probe design<sup>28</sup> and quantification.<sup>29</sup>

However, fluorescence and MR images were collected sequentially and separately. Accurate fusion of the images from different imaging modalities will need non-frigid

**Figure 7** Tomographic images by FMT and MRI.

**Notes:** (A) and (D) position of the cross section (red line). (B, C, E and F) MRI and fluorescence tomographic images of the selected slice. **Abbreviations:** au, arbitrary unit; FMT, fluorescence molecular tomography; MRI, magnetic resonance imaging.

registration, which is intrinsically difficult. In contrast, simultaneous image scanning by both modalities will benefit from the inherent registration due to fixed instrument geometry.<sup>30</sup> According to our previous investigation,<sup>31</sup> the spatial resolution achieved by hybrid FMT-CT was at least 1.2 mm. In our future work, we are planning to simultaneously implement FMT and MR imaging on a hybrid FMT-MRI system, which enables high accuracy FMT reconstruction<sup>21</sup> and offers high soft-tissue contrast, high resolution, and high sensitivity.<sup>30</sup>

In comparison with other dual-labeled NPs, IO-anti-EGFR-Cy5.5 NPs show excellent biocompatibility, satisfying colloidal stability, and enhanced MR contrast.<sup>24</sup> Furthermore, Cy5.5, as one representative NIRF dye, possesses the minimum absorbance spectra in the NIR region,<sup>32</sup> and enables characterization of deep diseased tissues.<sup>18</sup> Dual-modality magnetic-fluorescent NP, which imparts contrast in both imaging modalities, such as the one described herein, can extend the prospects of MRI-fluorescence imaging, and facilitate information cross-validation and direct comparison between different modalities.

In addition, the toxicity of magnetic NPs is under intense investigation.<sup>33</sup> According to our short-term (4.5 day) observation during the experiment, no side effects were observed on the mice after the probe injection. We will work on toxicity testing of the IO-anti-EGFR-Cy5.5 NP in the near future.

## Conclusion

We synthesized a dual-labeled NP (IO-anti-EGFR-Cy5.5), which facilitates the tomographic visualization of tumor targeting on the macroscopic level with MRI and FMT. Information cross-validation and direct comparison between different modalities were achieved. Dual-modality imaging, combining fluorescence imaging and MRI, may have great potential in accurate 3D visualization of tumor targeting and other molecular processes in vivo.

International Journal of Nanomedicine

Publish your work in this journal

The International Journal of Nanomedicine is an international, peer-reviewed journal focusing on the application of nanotechnology in diagnostics, therapeutics, and drug delivery systems throughout the biomedical field. This journal is indexed on PubMed Central, MedLine, CAS, SciSearch®, Current Contents®/Clinical Medicine,

Submit your manuscript here: <http://www.dovepress.com/international-journal-of-nanomedicine-journal>

Dovepress

Journal Citation Reports/Science Edition, EMBase, Scopus and the Elsevier Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
