Purpose: To evaluate the ability of enhanced-depth imaging (EDI) optical coherence tomography angiography (OCTA) to detect vascular signals inside the glaucomatous optic disc.

Patients and methods: Ten glaucomatous eyes of 8 subjects and 11 nonglaucomatous eyes of 7 subjects underwent EDI and conventional OCTA for optic disc analysis. The optic disc vessel density (VD) at maximum scan depth (2 mm) was compared between the 2 methods and between glaucomatous and nonglaucomatous eyes. Regression analysis was used to determine the factors affecting disc VD.

Results: The median (25th, 75th percentile) of the visual field mean deviation was -20.5 ($-25.1, -13.5$) dB in glaucoma. The disc VD measured with the EDI method was significantly greater than that measured with the conventional method in glaucoma and nonglaucoma. The disc VD was also significantly lower in glaucoma than in nonglaucoma. The disc VD and mean deviation were significantly and positively correlated in both methods (conventional: $R^2=0.27$, EDI: $R^2=0.22$).

Conclusion: The correlation between disc VD and glaucoma severity was comparable between conventional and EDI measurements. Images obtained with EDI-OCTA have the additional benefit of revealing more vascular signals in deeper layers. The disc VD, as determined by both conventional and EDI-OCTA methods, may be an indicator of glaucoma severity.

Keywords: optical coherence tomography angiography, enhanced-depth imaging, vessel density, glaucoma severity, mean deviation

Introduction

Glaucoma is a progressive disease that can cause irreversible vision loss and is the leading cause of blindness around the world.¹ Intraocular pressure (IOP) elevation is the only glaucoma-related abnormality for which treatment prevents disease progression,² but fundus fluorescein angiography studies suggest that glaucoma is associated with changes in the retinal vasculature and ocular circulation.³ However, some patients are allergic to fluorescein dye, with some potentially having a severe adverse reaction, including anaphylactic shock.

Optical coherence tomography angiography (OCTA) was recently developed as a method to study the retinal and peripapillary microvasculature without the need for dye injection.⁴ A recent OCTA study revealed changes in optic nerve head (ONH) vessel density (VD)⁵ while another study found a decrease in peripapillary VD in eyes with glaucoma.⁶ The decrease in peripapillary VD was detected prior to visual field (VF) defects in eyes with preperimetric glaucoma.⁷ The applicability of VD change analysis for glaucoma is somewhat controversial, but a prior study suggests that evaluating

ONH and peripapillary vasculature changes may be useful for monitoring glaucoma progression.⁵ Rao et al^{8,9} reported that the diagnostic ability of peripapillary VD was comparable to that of retinal nerve fiber layer thickness in eyes with primary open-angle glaucoma and primary angle-closure glaucoma. However, the diagnostic ability of macular and ONH VD measurements was reported to be significantly lower than peripapillary VD measurements.

The lamina cribrosa is made up of porous connective tissue and retinal ganglion cell axon bundles traveling through it to reach the orbital portion of the optic nerve. The lamina cribrosa plays a critical role in the pathogenesis of glaucoma.¹⁰ Faridi et al¹¹ reported an association between the presence of a focal lamina cribrosa defect and glaucoma progression. Additionally, Suh et al¹² reported a significant relationship between the presence of a focal laminar defect and a circumpapillary VD reduction. Another report showed that OCTA successfully detected pre-laminar VD reductions in glaucomatous eyes and that VD was significantly correlated with glaucoma severity.¹³

Spaide et al¹⁴ applied the enhanced-depth imaging (EDI) method to spectral-domain OCT (SD-OCT) to image deeper structures, including choroidal capillaries and vessels. These EDI-OCT images helped to elucidate choroidal disease etiology in several conditions, including central serous chorioretinopathy and Vogt–Koyanagi–Harada disease.¹⁴ The EDI method has also been used to image the lamina cribrosa and posterior lamina edge.¹⁵

The EDI technique is often used to enhance SD-OCT images, but has not yet been applied to OCTA. We hypothesized that using EDI with OCTA would be useful for detecting deep ONH vascular signals, particularly in laminar tissue. The purpose of the current study was to evaluate the ability of EDI-OCTA to detect deep vascular signals at the level of the lamina area in glaucomatous eyes.

Patient and methods

This cross-sectional, comparative, prospective study was reviewed and approved by the Ethics Committee of Saitama Medical University (Iruma, Japan). All subjects provided written informed consent to participate in the study, and all study conduct adhered to the tenets of the Declaration of Helsinki.

Study population

Patients with glaucoma that were at least 20 years old were considered for study enrollment. All screening examinations were conducted between April 2015 and March 2016

and included the following examinations: comprehensive ophthalmic examination (including slit-lamp biomicroscopy), IOP measurement (non-contact tonometry; Tonoref II, Nidek Co., Ltd., Aichi, Japan), gonioscopy, dilated fundus examination, fundus photography (CX-1, Canon Inc., Tokyo, Japan), axial length measurement (Optical Biometer OA-2000, Tomey Corp., Nagoya, Japan), automated VF assessment (24-2 Swedish Interactive Thresholding Algorithm [Carl Zeiss Meditec, Jena, Germany]), retinal nerve fiber layer thickness measurement (Spectralis HRA 2, Heidelberg Engineering, Heidelberg, Germany), and SD-OCTA (RS3000 Advance, Nidek Co., Ltd.).

Subjects were included in the glaucoma group if all of the following were present: glaucomatous optic neuropathy (based on fundus photography findings), glaucomatous VF damage (defined as a glaucoma hemifield test result outside normal limits and a pattern SD outside 95% of normal limits¹⁶), a nerve fiber layer defect consistent with the VF defect, and a VF mean deviation (MD) < -6 dB.

A group of subjects without glaucoma were included for comparison. Subjects were eligible for inclusion in the non-glaucoma (control) group if IOP was normal (< 20 mmHg) and glaucomatous optical neuropathy, nerve fiber layer defects, and glaucomatous VF defects were absent.

Subjects in both groups had the same exclusion criteria. Subjects were not included in the study if any of the following were true: age < 20 years, refractive error > +3 or < -6.0 diopters, axial length > 26 mm, evidence of other ocular disease (including diabetic retinopathy, retinal vein/artery occlusion, age-related macular degeneration, retinal detachment, tilted disc, and exfoliation syndrome), or poor image quality due to poor fixation or a cataract.

OCTA

All OCTA images were collected using an SD-OCT system (RS3000 Advance, Nidek Co., Ltd.). Images included a 3×3 mm² measurement area centered on the optic disc and were obtained using a central wavelength of 880 nm and an A-scan rate of 53,000 scans/s. Axial and transverse image resolution in the imaged tissue was 7 and 20 μm, respectively. The OCTA software was used to acquire a 3×3×2 mm³ image cube, with each cube consisting of 256 B-scans. Angiography signals were processed using both phase/Doppler shift and amplitude variation, also known as complex OCT signal difference analysis angiography (aka, CODAA). All OCTA scans were obtained with the conventional method and EDI method.

Optic disc vessel signal evaluation

The optic disc measurement area included tissue inside of the disc margin. The optic disc boundary was defined by manually identifying Bruch's membrane opening on OCTA B-scan images and plotting the Bruch's membrane openings on the OCTA en face image. Measurement depth was the whole scan depth (2 mm) and not segmented. Angiography signals were analyzed using ImageJ software (National Institutes of Health, Bethesda, MD, USA), which is capable of a Sauvola analysis to perform local adaptive thresholding binarization on OCTA images. This transformed vessel signals into yellow regions (Figure 1), which were then digitized and measured.¹⁷ The disc VD was calculated as the percentage of vessel signal obtained over the entire measurement area inside the optic disc.

Statistical analyses

Data for continuous variables are expressed as median (25th, 75th percentile). Differences between subjects with and

without glaucoma in characteristics and clinical features were tested for statistical significance using Fisher's exact and Mann–Whitney *U*-tests. Wilcoxon signed-rank tests and Mann–Whitney *U*-tests were used to compare disc VD differences obtained with the conventional method and EDI method in subjects with and without glaucoma. Regression was used to estimate the relationships between the disc VD with both methods and the MD value. All statistical analyses were performed using JMP statistical software (version 10.1, SAS Institute Inc., Cary, NC, USA), and statistical significance was defined as $p < 0.05$.

Results

All included glaucoma and control subjects were Japanese. Fourteen eyes from 7 subjects with glaucoma and 16 eyes from 8 subjects without glaucoma were included. Of these, 10 eyes with glaucoma and 11 eyes without glaucoma were eligible for analysis in this study. In the glaucoma group, 2 eyes were excluded due to early-stage glaucoma and the

Figure 1 Clinical examinations of a subject without glaucoma (**A**) and with glaucoma (**B**) are shown.

Notes: Fundus photography (a), VF testing (f), conventional OCTA (b–e), and EDI-OCTA (g–j). Blood flow in B-scan images is represented in red (c, d, h, and i). The images shown in (d and i) are magnified views of the green square in images (c and h) and show that EDI-OCTA detects more deep layer signals than conventional OCTA (red arrowheads). Binarized images (e and j; vessels shown in yellow) were analyzed for VD inside the ONH (yellow circle).

Abbreviations: IOP, intraocular pressure; MD, mean deviation.

other 2 eyes were excluded due to the presence of an epiretinal membrane. Five eyes from the subjects without glaucoma were excluded due to borderline VF abnormalities, which were not consistent with nerve fiber layer defect. Table 1 summarizes the subject and clinical characteristics of the 2 groups. There were no significant differences between the groups in age, sex, axial length, or IOP. However, the VF MD was significantly different in the glaucoma (-20.5 dB [-25.1, -13.5]) and control (-0.54 dB [-2.20, 0.00]) groups ($p < 0.01$, Table 1).

The disc VD measured via the 2 imaging methods was compared. The disc VD obtained using EDI was significantly higher than conventional measurements in both glaucomatous and nonglaucomatous eyes ($p < 0.01$, Figure 2). Additionally, disc VD was significantly lower in eyes with glaucoma than in eyes without glaucoma, regardless of which imaging method was used (conventional: $p = 0.03$, EDI: $p = 0.01$; Figure 2). Figure 3 shows the significant positive

linear correlation between MD and disc VD, which was significant for and comparable between both imaging methods (conventional: $R^2 = 0.27$, $p = 0.02$; EDI: $R^2 = 0.22$, $p = 0.02$).

Discussion

This study demonstrated that disc VD measurements obtained using EDI-OCTA were higher than those obtained using the conventional method. This finding implies that EDI-OCTA can detect more vessel signals in the deep ONH layer than the conventional method. The disc VD was significantly correlated with glaucoma severity when disc VD was measured with both the conventional method and EDI-OCTA. Additionally, the correlation equation was comparable between imaging methods.

Several recent reports examined the relationship between glaucoma and disc VD reduction in the circumpapillary area and inside the ONH.^{5,7,13,18} Previous reports^{13,18} used conventional OCTA to show that pre-laminar and ONH tissue VDs were significantly lower in patients with glaucoma than in patients without glaucoma. The current study also found that disc VD was significantly lower in patients with glaucoma than in patients without glaucoma when disc VD was measured with both conventional imaging and EDI (Figure 2). Additionally, the correlation equations between disc VD reduction and glaucoma severity (Table 2; Figure 3) were similar when disc VD reduction was measured with either imaging method. Therefore, disc VD measurements may be useful for monitoring disease progression in eyes with moderate-to-advanced glaucoma, particularly when disc VD is measured using EDI, which can detect more vascular signals in the deep ONH layer. This study only included glaucoma patients that had an MD of -6.0 dB or worse, and further studies are needed to examine the usefulness of disc VD measurements in eyes with early-stage glaucoma.

Fluorescein fundus angiography and laser Doppler flowmetry measurements indicate that optic disc blood flow

Figure 2 VD measurements obtained with conventional imaging (dark gray) and EDI-OCTA (light gray).

Notes: Median disc VD in subjects without glaucoma was 23.2% (25th, 75th percentile: 21.0%, 30.3%) with conventional imaging and 29.4% (27.0%, 35.7%) with EDI. Disc VD was measured to be 19.3% (17.0%, 22.3%) with conventional imaging and 26.0% (23.6%, 27.7%) with EDI in subjects with glaucoma. *Mann-Whitney U-test. **Wilcoxon signed-rank test. is lower in eyes with glaucoma than in healthy eyes.^{19,20} Pre-laminar VD measurements made with OCTA also show that VD is lower in eyes with glaucoma than in eyes without glaucoma.^{13,21} These findings and those of the current study suggest a correlation between glaucoma progression and vascular changes. However, this remains controversial because some investigators have argued that the correlation is based on the “vascular theory.” This theory considers glaucomatous optic neuropathy to be a consequence of an inadequate blood supply,²² perhaps from secondary capillary loss that may result from retinal nerve fiber layer damage.⁶

The ONH microvasculature, particularly in the lamina cribrosa, is thought to play an important role in the pathogenesis of glaucoma. However, few studies have investigated deep layer vasculature changes in the lamina area of glaucomatous eyes.²³ Although EDI is widely used for measuring lamina cribrosa thickness,¹⁵ there are no reports of the use of EDI with OCTA in the literature. The present study shows that EDI-OCTA detected more ONH vessel signals than conventional OCTA. Even though glaucoma severity–disc VD reduction correlation equations were similar between the 2 imaging methods, EDI-OCTA detected lamina cribrosa vessel signals to a deeper level than conventional OCTA

in eyes with and without glaucoma (Figures 1 and 2). This is important because studying the deep layer lamina area vasculature may improve our understanding of glaucoma pathogenesis.

Our study had several limitations. First, this study was designed as a preliminary study. Therefore, our sample size was relatively small, and data were included from both eyes. Additionally, subjects were not categorized by glaucoma severity. Further studies that include a larger number of subjects are needed to better understand the association between glaucoma stage and disc VD. Second, we did not evaluate the reliability and reproducibility of OCTA in this study. However, in a study involving macular analysis, Al-Sheikh et al²⁴ reported good reproducibility of OCTA examinations with RS3000 Advance. This suggests that our OCTA examinations also might have good reproducibility. Third, prior studies have shown that EDI is superior to standard imaging methods for measuring lamina thickness.¹⁵ However, OCTA signals of whole lamina tissue could not be obtained, even when using EDI, and it is difficult to distinguish between deeper vessel signals and shadow artifacts. Fourth, VD measurement variability between imaging system software created some challenges. Image analyses

Table 2 Univariate regression analysis for factors affecting MD value

Variables	Conventional method		EDI method	
	β (95% CI)	p -value ^a	β (95% CI)	p -value ^a
Age (years)	-0.20 (-0.66, 0.27)	0.39	-0.02 (-0.39, 0.36)	0.93
Sex (ref. women)	-0.93 (-3.64, 1.76)	0.48	-0.44 (-2.57, 1.69)	0.67

were performed using a selected binarization algorithm to define signal thresholds. It was difficult to know which of the numerous available algorithms were best for determining VD. Therefore, future studies should evaluate binarization feasibility, reproducibility, and standardization. Fifth, unstable fixation for advanced-stage glaucoma patient may hamper OCTA image detection as it hampers VF testing. Further OCTA research to investigate glaucoma patients who cannot maintain fixation during VF testing would be helpful. Finally, superficial signals affected deeper layer VD measurements by creating projection artifacts. Therefore, VD measurements of the large, superficial lamina cribrosa vessels may not have been accurate because imaging signals were sometimes obscured by large superficial vessels overlying deeper tissue (creating image shadows). This issue is common when measuring VD using OCTA, and it is especially difficult to distinguish between true deeper vessel signals and these artifacts in EDI-OCTA. So, further studies are needed to isolate laminar capillary signals by excluding superficial vessel signals (eg, projection artifact removal software²⁵).

Conclusion

The correlation between the disc VD and glaucoma severity was significant and had a similar coefficient value when disc VD was measured with EDI-OCTA and conventional OCTA. EDI-OCTA detected deeper optic disc vessel signals than did the conventional method. The disc VD, as determined by both conventional and EDI-OCTA methods, may be an indicator of glaucoma severity. Further research is needed to determine if a decrease in deep laminar VD is a risk factor for glaucoma development and progression.
