Background: Prophylactic noninvasive ventilation (NIV) after scheduled extubation can benefit patients with chronic respiratory disorders, among which chronic obstructive pulmonary disease (COPD) is a significant example. However, it is not known whether all COPD patients benefit from prophylactic NIV.

Methods: We performed a post hoc analysis of prospectively collected data. COPD patients who successfully completed a spontaneous breathing trial were enrolled. In the prophylactic NIV group, NIV was applied immediately after extubation. In the usual care group, conventional oxygen therapy was used. Patients were followed up to 90 days post-extubation.

Results: Among patients with $\text{PaCO}_2 > 45$ mmHg, 128 and 40 received prophylactic NIV and usual care, respectively. Prophylactic NIV led to lower rates of re-intubation (4% vs 30% at 72 h and 11% vs 35% at 7 days, both $p < 0.01$) and hospital mortality (18% vs 40%, $p < 0.01$) than usual care. The proportion of 90-day mortality was also lower in the prophylactic NIV group (log rank test, $p = 0.04$). Among patients with $\text{PaCO}_2 \leq 45$ mmHg, 32 and 21 received prophylactic NIV and usual care, respectively. In this cohort however, prophylactic NIV neither reduced re-intubation (6% vs 5% at 72 h, $p > 0.99$, and 9% vs 14% at 7 days, $p = 0.67$) nor hospital mortality (19% vs 24%, $p = 0.74$). The proportion of 90-day mortality did not differ between the two groups (log rank test, $p = 0.79$).

Conclusion: This exploratory study shows that prophylactic NIV benefits COPD patients with $\text{PaCO}_2 > 45$ mmHg, but it may not benefit those with $\text{PaCO}_2 \leq 45$ mmHg. Further study with a larger sample size is required to confirm this.

Keywords: noninvasive ventilation, ventilator weaning, re-intubation

Introduction

Chronic obstructive pulmonary disease (COPD) is a worldwide public health challenge, due to its high prevalence and related disability and mortality.¹ It is the fourth leading cause of death worldwide and the third in China.^{2,3} Among COPD patients who receive invasive mechanical ventilation, hospital mortality reaches 30%.⁴ Investigation of how to reduce mortality in critically ill COPD patients is needed.

Noninvasive ventilation (NIV) is widely used to liberate patients from invasive mechanical ventilation. NIV is performed immediately following endotracheal tube removal (prophylactic use) in patients who successfully complete a spontaneous breathing trial (SBT) to avoid extubation failure. Prophylactic NIV reduces extubation failure in high-risk patients but not in the overall population.⁵⁻⁹ Therefore, guidelines recommend that NIV be used preventively in high-risk patients.^{10,11} COPD is a risk

factor for extubation failure.^{12,13} It has been demonstrated that prophylactic NIV benefits patients who exhibit this risk factor.^{6,7} However, it remains unclear whether all COPD patients benefit from prophylactic NIV. For this reason, we identified COPD patients who could benefit from prophylactic NIV.

Methods

From 2011 to 2018, we developed a database in an intensive care unit (ICU) of a teaching hospital and prospectively collected data for patients who were ready for extubation after successful SBT. In this study, we enrolled patients diagnosed with COPD. Data on some patients taken from a previous study were analyzed as well.¹⁴ However, patients with tracheotomies were excluded. The study protocol was approved by the local ethics committee (the First Affiliated Hospital of Chongqing Medical University). Due to the observational nature of this study, informed consent was waived. We declare that all the data which can identify the personal information has been hidden. And all the interventions are performed as our hospital protocol, which is according with the Declaration of Helsinki.

Patients admitted to our ICU were managed following hospital protocols. COPD was diagnosed based on the criteria published by Chinese Medical Association.¹⁵ Bronchodilators such as salbutamol and budesonide were used to reduce airway resistance for patients who received invasive mechanical ventilation. Expectorants such as acetylcysteine were used to diminish airway secretions. Sedation and analgesia were used to promote patient-ventilator interaction. At the beginning of ventilation, the assist/control mode was used. After respiratory failure was reversed, pressure support ventilation (PSV) was used to facilitate ventilator weaning.

We screened the patients every morning to identify those who could be liberated from invasive mechanical ventilation. A SBT was performed if the following criteria were met: reversal of the underlying cause of acute respiratory failure, positive end-expiratory pressure (PEEP) ≤ 5 cmH₂O, FiO₂ $\leq 50\%$, PaO₂/FiO₂ ≥ 150 , temperature $\leq 38^\circ\text{C}$, heart rate ≤ 120 beats/min, breathing frequency ≤ 30 cycles/min, and hemodynamic stability.¹⁴ PSV was used to perform a 120 min SBT. Support pressure was set at 6 and 8 cmH₂O for inner diameters of the endotracheal tube of ≥ 7.5 and < 7.5 mm, respectively.^{16,17} SBT failure was defined as the presence one of the following criteria: heart rate ≥ 140 or ≤ 50 beats/min, breathing frequency ≥ 35 cycles/min, rapid shallow breathing index (f/V_T) > 105 , peripheral oxygen saturation (SpO₂) $<$

90% at FiO₂ $\geq 50\%$, systolic blood pressure ≥ 180 or ≤ 90 mmHg; diminishing consciousness or diaphoresis; and clinical signs indicating respiratory muscle fatigue, labored breathing, or both. The endotracheal tube was removed if there were no signs of SBT failure.

Following their attending physicians' orders, after extubation, patients received immediate use of NIV or conventional oxygen therapy. Based on existing evidence, physicians were more likely to order prophylactic NIV in patients at risk for extubation failure.⁶⁻⁹ In our department, we used BiPAP Vision and V60 (Philips Respironics, Monroeville, PA, USA) to perform NIV. The S/T mode was selected. At the beginning of NIV, the expiratory positive airway pressure was set at 4 cmH₂O and gradually increased to counterbalance the intrinsic PEEP. The initial inspiratory pressure was set at 8 cmH₂O and gradually increased to reach a tidal volume of around 8 mL/kg or to the maximum tolerated level for each patient. The FiO₂ was set to maintain SpO₂ around 95%. After 24 h, liberation from NIV was considered, following hospital protocol.¹⁸ In patients who received conventional oxygen therapy, a nasal cannula or mask was used. Oxygen flow was adjusted to maintain SpO₂ around 95%.

Reintubation was determined based on the protocol of our hospital (one major criterion or at least two minor criteria).¹⁴ The major criteria were loss of consciousness, heart rate < 50 beats/min with loss of alertness, respiratory arrest, development of conditions necessitating intubation to protect the airway (coma or seizure disorders) or copious tracheal secretions requiring management, and hemodynamic instability without response to fluids and vasoactive drugs. The minor criteria were hypoxemia with PaO₂ < 60 mmHg at FiO₂ > 0.5 or supplemental oxygen flow > 10 L/min, acidosis with pH < 7.30 , breathing frequency > 35 cycles/min, persistent tachycardia, and persistent activation of accessory respiratory muscles.

At extubation, we recorded the age, gender, acute physiology and chronic health evaluation II score, heart rate, breathing frequency, blood pressure, Glasgow coma scale, hemoglobin, and duration of ventilation. We recorded reintubation at 72 h and 7 days post-extubation. We also recorded ICU stay, hospital stay, ICU mortality, and hospital mortality. Patients were followed up to 90 days or death, whichever came first.

PaCO₂ was measured at the end of SBT. A previous study reported that prophylactic NIV benefited patients with PaCO₂ greater than 45 mmHg when measured at

extubation.⁷ We used this cutoff value to divide the patients into two cohorts.

Statistical Analysis

Normally distributed continuous variables are reported as mean and standard deviation. Non-normally distributed continuous variables are reported as medians and interquartile ranges. The differences between the groups were analyzed using the independent-sample *T*-test or the Mann–Whitney *U*-test when appropriate. Categorical variables are reported as numbers and percentages, and differences between groups were analyzed using the chi-square and/or Fisher's exact test when appropriate. Kaplan–Meier analysis was used to indicate survival probability. A *p* value less than 0.05 was taken to indicate statistical significance.

Results

We enrolled 168 patients with PaCO₂ > 45 mmHg. Of these, 128 cases received prophylactic NIV, and 40 cases received conventional oxygen therapy. Another 53 patients were enrolled with PaCO₂ ≤ 45 mmHg. Of these, 32 cases received prophylactic NIV, and 21 cases received

conventional oxygen therapy. The demographics collected at extubation are summarized in Table 1.

In the cohort with PaCO₂ ≤ 45 mmHg, the NIV group had a longer duration of invasive mechanical ventilation before extubation than the control group (with medians [interquartile ranges] of 5 [3–9] vs 4 [2–6] days, *p* = 0.04). In the cohort with PaCO₂ > 45 mmHg, the NIV group had lower hemoglobin than the control group (11.7±2.3 vs 12.8±2.1 g/dL, *p* = 0.01). There were no differences between the NIV and control groups in either cohort for other variables.

In the cohort with PaCO₂ ≤ 45 mmHg, there were no differences in the re-intubation rate, hospital mortality, 90-day mortality, ICU stay, or hospital stay between the NIV and control groups (Table 2). The crude and adjusted odds ratios (ORs) for re-intubation at 7 days were 0.62 (95% confidence interval [CI], 0.11–3.41, *p* = 0.58) and 0.35 (95% CI, 0.04–2.79, *p* = 0.32). In the cohort with PaCO₂ > 45 mmHg, the NIV group had a lower re-intubation rate and hospital mortality. The crude and adjusted OR of re-intubation at 7 days were 0.23 (95% CI, 0.10–0.54, *p* < 0.01) and 0.17 (95% CI, 0.07–0.46, *p* < 0.01).

There was no difference in cumulative survival between the NIV and control groups in the PaCO₂ ≤ 45 mmHg cohort

(log rank test, *p* = 0.79) (Figure 1). However, in the cohort with PaCO₂ > 45 mmHg, it was much lower in the NIV group than in the control group (log rank test, *p* = 0.04) (Figure 2).

Discussion

Our study systematically explored the effects of prophylactic NIV in COPD patients. In the cohort with PaCO₂ ≤ 45 mmHg, prophylactic NIV did not reduce re-intubation or hospital mortality. In the cohort with PaCO₂ > 45 mmHg, prophylactic NIV significantly reduced re-intubation and hospital mortality.

The physiological effects of NIV in COPD patients counterbalance the intrinsic PEEP, which decreases the work of breathing.¹⁹ Therefore, NIV is widely used in the process of

ventilator weaning.²⁰ A recent systematic review and meta-analysis showed that NIV as a weaning strategy reduced re-intubation in COPD population (relative risk = 0.33).²¹ However, in our study, we challenged the assumption that all COPD patients benefit from prophylactic NIV. We found that prophylactic NIV benefited COPD patients with PaCO₂ > 45 mmHg but not in those with PaCO₂ < 45 mmHg. This is a new insight into the effects of NIV on ventilator weaning.

To the best of our knowledge, only one study has explored the effects of prophylactic NIV in COPD patients.²² However, its sample was limited to 20 patients in each group. This small sample size failed to show any benefits from NIV. A further three studies have explored the effects of prophylactic NIV in patients with chronic

Figure 1 Survival in patients with PaCO₂ ≤ 45 mmHg.

Figure 2 Survival in patients with PaCO₂ > 45 mmHg.

respiratory disorders.^{7,8,23} These studies showed that patients with chronic respiratory disorders benefit from prophylactic NIV. However, COPD was only one of the chronic respiratory disorders reviewed. Those studies also failed to unequivocally demonstrate whether COPD patients could benefit from prophylactic NIV. Therefore, the use of prophylactic NIV in COPD patients has remained controversial. Because our study enrolled 221 COPD patients, it enabled us to conduct a subgroup analysis based on the level of PaCO₂ measured at extubation, which constitutes a major strength of this study. Furthermore, we found that prophylactic NIV benefited COPD patients with hypercapnia but not non-hypercapnic patients. This can provide a reference for decision makers as they consider how to use NIV in COPD patients after a scheduled extubation.

Among the low-risk patients who received conventional oxygen therapy after a planned extubation, the rate of re-intubation at 72 h post-extubation was 12.2%.²⁴ Among patients with PaCO₂ ≤ 45 mmHg, the re-intubation rates at 72 h post-extubation were 6% and 5% in the NIV and control groups, respectively. This indicates that these patients had a low risk of re-intubation. A previous study demonstrated that prophylactic NIV did not reduce re-intubation or ICU mortality in patients with a low risk of re-intubation.⁵ Therefore, prophylactic NIV may not benefit COPD patients with PaCO₂ ≤ 45 mmHg. However, a recent study reported that high-risk patients with PaCO₂ ≤ 45 mmHg reduced re-intubation.²⁵ In this study, only 18% of patients were diagnosed with COPD in the cohort with PaCO₂ ≤ 45 mmHg. It means that these patients had other risk factors for re-intubation. Therefore, COPD patients with PaCO₂ ≤ 45 mmHg may benefit from prophylactic NIV if they feature other risk factors for re-intubation.

A previous study classified the reasons for re-intubation as airway and non-airway failure.²⁶ Airway failure was the inability to breathe without a tracheal tube due to airway obstruction resulting from aspiration or excessive respiratory secretions. Non-airway failure might lead to an inability to breathe without mechanical ventilation due to congestive heart failure, lung disease, or hypoventilation. In the COPD population, PaCO₂ is negatively correlated with tidal volume and pulmonary function.²⁷ Patients with higher PaCO₂ may have lower tidal volumes and worse pulmonary function.²⁷ Therefore, the proportion of non-airway failure may be higher in patients with PaCO₂ > 45 mmHg than in those with PaCO₂ ≤ 45 mmHg. NIV can improve outcomes among patients at risk for non-airway failure because it can improve alveolar ventilation and reduce the work of

breathing.²⁸ However, it is difficult to manage risk factors for non-airway failure. This may be a reason for difficult re-intubation rates among patients with PaCO₂ ≤ 45 and >45 mmHg when they have received NIV care.

Our study had several limitations. As it was an observational study, the use of prophylactic NIV was decided by the attending physicians. Patients at high risk for extubation failure were more likely to receive prophylactic NIV than patients with low risk. Hypercapnic patients were more likely to receive prophylactic NIV. This resulted in selection bias. In addition, we only enrolled 53 COPD patients with PaCO₂ ≤ 45 mmHg. This might have limited statistical power and made it inadequate to conclude that prophylactic NIV did not benefit COPD patients with PaCO₂ ≤ 45 mmHg. Further studies with larger sample sizes are required to confirm this result.

Conclusions

This exploratory study shows that prophylactic NIV benefits COPD patients with PaCO₂ > 45 mmHg, but it may not do so in those with PaCO₂ ≤ 45 mmHg. Further studies with larger sample sizes are required to draw more robust conclusions on this issue.

International Journal of Chronic Obstructive Pulmonary Disease

Dovepress

Publish your work in this journal

The International Journal of COPD is an international, peer-reviewed journal of therapeutics and pharmacology focusing on concise rapid reporting of clinical studies and reviews in COPD. Special focus is given to the pathophysiological processes underlying the disease, intervention programs, patient focused education, and self management

protocols. This journal is indexed on PubMed Central, MedLine and CAS. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
