Background: *Helicobacter pylori* is a cause of gastric cancer, and thus the eradication of this bacterium is very important. The success rate of primary eradication has been dramatically increased by the introduction of potassium-competitive acid blockers. However, *H. pylori* cannot be eradicated in all patients, and the contributing factors need to be clarified.

Aim: Because allergy status may be a factor and considering research linking hay fever with eradication failure, the purpose of this study was to examine blood immunoglobulin E levels as a contributing factor in patients who were unable to eradicate *H. pylori* in a single eradication treatment and who underwent multiple eradication attempts.

Methods: Questionnaire data were collected from 250 patients who visited the Department of Gastroenterology, Hamamatsu University School of Medicine, for *H. pylori* eradication. In addition, non-specific IgE levels in the blood were measured and analyzed with one-way analysis of variance. Multinomial logistic regression analysis was performed to examine the association between the number of eradication attempts and the IgE level (< 500 vs \geq 500 IU/mL).

Results: The mean IgE values were 188.4, 211.9, and 744.0 IU/mL in patients with one, two, and three or more eradication attempts, respectively ($P < 0.05$). The results of multinomial logistic regression analysis showed that attempting eradication three or more times was significantly associated with high levels of IgE, even after consideration of antibiotic sensitivity.

Conclusion: *H. pylori* eradication was less likely in patients with high IgE. It is thus necessary to study the appropriate regimen for patients with high IgE levels.

Keywords: *Helicobacter pylori*, multiple eradication, antibiotic sensitivity

Introduction

Previous research has shown that *Helicobacter pylori* causes gastric ulcers and gastric cancer¹⁻⁴ and that eradication of *H. pylori* can reduce the risk of gastric cancer.^{5,6} Therefore, successful eradication is vital.

In Japan, the eradication rate with the use of amoxicillin/clarithromycin/proton-pump inhibitor combination therapy as first-line therapy is reported to be 60% to 70%.^{7,8} In 2015, the proton-pump inhibitor was replaced with vonoprazan, which is a potassium-competitive acid blocker (P-CAB), and this dramatically increased the success rate of primary eradication to about 90%.⁹ However, eradication is not possible in some people, and clarification of the contributing factors is important. We previously reported that eradication failure is associated with hay fever¹⁰ and with alcohol consumption in female patients.¹¹

In the present study, we examined the blood IgE levels of patients who were unable to eradicate *H. pylori* despite multiple attempts, considering the possibility that patients' physical constitution might be a contributing factor. Although there have been several analyses of the blood parameters of patients with *H. pylori* infection, few studies have described the relationship between patients' blood parameters and eradication.

Therefore, the purpose of this study was to examine blood IgE levels as a contributing factor in patients who were unable to eradicate *H. pylori* in a single eradication treatment and who underwent multiple eradication attempts. We focused on IgE levels, which are caused by patient's allergy status, because we previously found that *H. pylori* eradication was less likely in patients with hay fever. In particular, we sought to clarify the relationship between the difficulty of eradication and the raw IgE values, as well as the relationship with high and low IgE levels. We also took into account antibiotic sensitivity.

Materials and Methods

Completed questionnaires and blood test data were obtained from 250 patients who visited the Department of Gastroenterology of Hamamatsu University School of Medicine for *H. pylori* eradication between April 2017 and December 2020. Patient consent was obtained after written explanation of the study aims. The questionnaire items included sex, age, alcohol consumption, smoking, previous eradication experience, and number of previous eradication attempts. In addition, non-specific IgE levels in the blood were measured. The test method applied was fluorescence enzyme immunoassay (FEIA), a type of enzyme immunoassay in which an antigen-antibody reaction is achieved using antigens or antibodies labeled with enzymes on labeled substances and the fluorescence intensity of the fluorescent substrate is measured. The exclusion criterion was no response to the required items.

Because the patients came to the university hospital for eradication, many of them had experienced failed eradication at least once at their general practitioners or at other hospitals. Amoxicillin, clarithromycin, and vonoprazan were used for primary eradication, whereas amoxicillin, metronidazole, and vonoprazan were used for secondary eradication. After the third eradication attempt, the choice of treatment was left largely to the physicians' discretion. In many cases, sitafloxacin and minocycline were used instead of amoxicillin.

We performed a simple tabulation of the attributes of 250 patients who visited the Department of Gastroenterology, Hamamatsu University School of Medicine, for *H. pylori* eradication, including sex, age, and other characteristics (Table 1). Next, 26 patients with autoimmune gastritis who did not have *H. pylori* infection were excluded. Furthermore, patients who had never undergone eradication were excluded, and 151 patients who had undergone eradication at least once were selected. We divided the patients into three groups (one, two, and three or more eradication

Table 1 Patients' Demographic Characteristics

Characteristic	n	%

Patients with autoimmune gastritis (not <i>H. pylori</i> infection)	26	10.4

attempts), assessed the mean values of non-specific IgE levels, and performed a one-way analysis of variance (Table 2), which was the exclusion criterion.

In addition, regarding the eradication difficulty, multinomial logistic regression analysis was performed to examine the association between the number of eradication attempts and the level of IgE (dichotomized as < 500 and ≥ 500 IU/mL) (Table 3).

In model 1, IgE level (with low as reference) was used as the independent variable, and the number of eradication attempts (with one as reference) was used as the dependent variable. In model 2, clarithromycin sensitivity was added as a covariate. We examined the susceptibility to clarithromycin by blood tests. The susceptibility values were < 0.015 , 0.03 , 0.06 , 2 , 4 , 8 , 16 , 32 , and 64 $\mu\text{g/mL}$. The threshold for clarithromycin susceptibility was set at 1 $\mu\text{g/mL}$ using the criteria recommended by the American Board of Clinical and Laboratory Standards Institute (CLSI) and the Japanese Society for Chemotherapy. In model 3, clarithromycin susceptibility, sex, age, presence of alcohol consumption, and smoking were added as covariates for analysis.

Statistical analysis was performed using SPSS version 24. A P-value < 0.05 was considered statistically significant.

Results

The patients' demographic characteristics are shown in Table 1. Because our patients visited a university hospital

rather than a general practitioner for eradication, they were considered to be a characteristic group and not a general population group. Most patients were over the age of 61 years. The reported lifestyle habits of the patients included alcohol intake and smoking. About 80% of the patients had been tested for *H. pylori* and 60% had been treated for eradication. In addition, 40% of the patients had undergone eradication treatment more than once. Meanwhile, about 10% of the patients with autoimmune gastritis had come to the hospital for *H. pylori* eradication but did not actually have *H. pylori* infection.

Table 2 shows the relationship between the number of eradication attempts and IgE levels using one-way analysis of variance. The mean IgE values were 188.4, 211.9, and 744.0 IU/mL in patients with one, two, and three or more eradication attempts, respectively ($P < 0.05$). The overall mean was 296.7 IU/mL, which was higher than the standard value of 173 IU/mL or less with the FEIA method.¹²

Table 3 shows the association between the number of eradication attempts (with one eradication as reference) and high IgE (≥ 500 IU/mL) and low IgE (< 500 IU/mL) levels using multinomial logistic regression analysis (with low IgE as reference). In all models, there was no significant association between two eradication attempts and high IgE levels, although eradication was slightly more difficult compared with a single eradication. However, in all models, attempting eradication three or more times was significantly associated with high IgE levels.

Discussion

To our knowledge, this is the first study to examine the relationship between the difficulty of *H. pylori* eradication and the IgE level. Our results suggest that eradication failure is more common in patients with high IgE levels and that such patients may require multiple eradication attempts. The patients who visited our university hospital were considered to be resistant to *H. pylori* eradication because they had previously experienced *H. pylori*

Table 2 Association Between the Number of Eradication Attempts and IgE Levels

Number of Eradication Attempts	n	Mean IgE, IU/mL	SD	P-value
One	44	188.4	244.6	0.004
Two	81	211.9	395.2	
Three or more	26	744.0	1612.6

eradication failure at general practitioners or in private hospitals or had adverse effects from eradication drugs. If there is an attribute of patients that hinders *H. pylori* eradication, it may be related to their high IgE levels.

Several previous studies have reported an association between allergic diseases and *H. pylori*. For instance, inverse associations of *H. pylori* with allergic rhinitis¹³ and asthma¹⁴ have been reported. Another earlier study mentioned that *H. pylori* neutrophil-activating protein could be an important candidate for novel strategies in the prevention and treatment of asthma and allergic diseases.^{15,16}

We considered IgE levels above 500 IU/mL to be high. We used this threshold because several previous studies have used IgE levels of 500 IU/mL or higher as high or reference values.^{17–20}

In the present study, patients with higher IgE levels were more frequently treated for *H. pylori* eradication (Table 2). This suggests that people who have difficulty eradicating *H. pylori* may show a tendency for high IgE levels. However, because susceptibility to clarithromycin was not considered, we further analyzed the results by taking susceptibility into account, given that many Japanese are resistant to clarithromycin.²¹

As shown in Table 3, we used multinomial logistic regression because the dependent variable was divided into three levels: one, two, and three or more eradication attempts. Model 1 is the crude model. Model 2 in Table 3 shows the results of the analysis with the addition of clarithromycin sensitivity. In model 3, susceptibility, sex, age, alcohol consumption, and smoking status were added as covariates. The results showed that high IgE levels were associated with a high number of eradication attempts, even when antimicrobial susceptibility was taken into account. These findings thus suggest that IgE influences eradication difficulty.

According to previous research, an increase in IgE-containing plasma cells results in various non-specific chronic inflammatory disorders of the upper gastrointestinal tract.²² In addition, the number of IgE-positive cells is significantly elevated in patients with chronic gastritis compared with normal mucosa and is accompanied by a significant accumulation of IgE-positive plasma cells in patients with *H. pylori*-positive gastritis, suggesting that IgE-mediated immune responses play an important role in the development of *H. pylori*-associated gastritis.^{23,24} Furthermore, prolonged *H. pylori* infection has been reported to promote the production of specific IgE

antibodies.²⁵ These findings suggest that IgE is closely related to *H. pylori* infection and that patients with long-term *H. pylori* infection may have high IgE levels. This may lead to the difficult eradication.

A study related to allergy showed that when an *H. pylori*-infected stomach is ulcerated, the regulatory T cell response is insufficient. Although this is a hypothesis, regulatory T cell-mediated suppression of inflammation and the bactericidal activity of epithelial cells may influence the increase in *H. pylori* density and the maintenance of prolonged bacterial colonization.²⁶ In this context, allergic individuals may have an imbalance in regulatory T cells, which may be an unstable factor that exacerbates the pathogenesis of *H. pylori* infection. A decrease in regulatory T cells causes downregulation of adaptive immunity and promotes persistence of *H. pylori* infection.²⁷ Regulatory T cells suppress T2 cells to prevent allergies but IgE production increases when this suppression is no longer effective and cytokines released by T2 cells stimulate B cells. In view of the above hypothesis, people with high IgE levels may have a higher density of *H. pylori* and prolonged bacterial colonization. A previous study examining the relationship between the eradication rate of *H. pylori* and *H. pylori* density found that the higher the bacterial density of *H. pylori*, the significantly more difficult its eradication.²⁸

There are four main limitations to this study. First, the frequency of eradication was self-reported by the patients; however, patients have to take many types and doses of eradication medicines for a week and it is unlikely that they mistook how many times they took the eradication medication. Second, as mentioned above, the target population is biased because it consisted of patients who visited a university hospital. However, because the patients were from a university hospital, we were able to conduct a survey of individuals who had undergone multiple eradication attempts, which is rarely seen in patients who generally visit clinics. Third, we do not know the patients' adherence to the medication. However, we believe that because the patients had already undergone more than one eradication attempt, they had a strong desire to achieve eradication, which should lead to good adherence. Fourth, we were not able to measure specific IgE in this study. Further studies are needed to investigate allergic factors in more detail.

The eradication rate of *H. pylori* has increased dramatically since the prescription of eradication drugs was changed in 2015. However, despite the increased

eradication success rate, *H. pylori* eradication may still be difficult in some people, which may be due to patient factors. Factors that might contribute to *H. pylori* eradication failure in patients with high IgE levels include long-term infection, because prolonged *H. pylori* infection promotes the production of specific IgE antibodies, and increased *H. pylori* density, which makes bacteria eradication more difficult.

In this study, we found that patients with high IgE levels were less likely to achieve *H. pylori* eradication, suggesting that individuals with high IgE should be more cautious when taking *H. pylori* eradication medication because they may have a constitution that hampers its eradication. In addition, the appropriate regimen for patients with high IgE levels should be studied.

Conclusion

Our analysis shows that, even after consideration of antibiotic sensitivity, patients with high IgE levels are less likely to eradicate *H. pylori*. Therefore, patients with high IgE need to be more cautious when taking *H. pylori* eradication drugs. IgE is closely related to *H. pylori* infection and patients with long-term *H. pylori* infection may have high IgE levels.
