Purpose: There is probably a high prevalence of small intestinal bacterial overgrowth (SIBO) in patients with gallbladder polyps (GBPs). To date, no study has evaluated the occurrence of SIBO in patients with GBPs. The aim of this study was to investigate the prevalence of SIBO in patients with GBPs and explore the possible association between these two conditions.

Patients and Methods: The hydrogen-methane breath test was used to diagnose SIBO, and patients were divided into GBPs and control groups based on whether GBPs were found under ultrasound. Clinical and paraclinical factors were compared between the two groups.

Results: A total of 297 subjects were included in this study. The prevalence of SIBO was significantly higher in the GBPs group than in the control group (50.0% vs.30.8%, $p < 0.01$). Multivariate logistic regression analysis showed that male (OR=2.26, 95% CI=1.12–4.57, $p = 0.023$), SIBO (OR=3.21, 95% CI=1.69–6.11, $p < 0.001$), fatty liver (OR=2.91, 95% CI= 1.50–5.64, $p = 0.002$) and BMI (OR=1.13, 95% CI=1.01–1.26, $p = 0.035$) were independently associated with GBPs. And by subgroup analysis, we found that the association between SIBO and GBPs was stronger in females than in males (p for interaction < 0.001). In addition, SIBO (OR=5.11, 95% CI=1.42–18.36, $p = 0.012$) and fasting glucose (OR=3.04, 95% CI=1.27–7.28, $p = 0.013$) were found to be associated with solitary polyps.

Conclusion: SIBO was highly prevalent in patients with GBPs, and this association seemed to be stronger among females.

Keywords: gut microbiota, bacterial overgrowth, breath test, gallbladder polyps

Introduction

Polypoid lesions of the gallbladder are one of the most commonly detected gallbladder diseases in adults on abdominal ultrasonography. Gallbladder polyps (GBPs) are usually asymptomatic, but in a few cases, they may present with symptoms similar to those of acute cholecystitis due to their specific anatomical location or when polyp fragments detach and obstruct the bile duct.¹ Most GBPs are generally considered benign, but a small percentage of GBPs were reported to have malignant potential.² According to the European joint guidelines,^{3,4} cholecystectomy is suggested for individuals with GBPs ≥ 10 mm in diameter; moreover, cholecystectomy is also recommended if the patient has a 6–9 mm polyp and one or more risk factors. Although a single polyp larger than 10 mm is by far the most consistent predictor of potential malignancy, many cases of malignant transformation of small polyps have been reported.^{2,5,6} The currently reported risk factors for GBPs include male sex, obesity, hypertension, hyperlipidemia, fatty liver, etc.^{7–10} However, the conclusions of these studies are inconsistent, and the differences may be due to variations in geography, ethnicity and study design. Gallbladder cancer has a very low 5-year survival rate, and early detection is difficult due to the lack of obvious symptoms. Considering that GBPs constitute an important risk factor for gallbladder cancer, the identification of etiology and relevant factors of GBPs is crucial for early screening and developing rational clinical strategies.

Gut microbiota is one of the most complex and important micro-ecosystems in the human body. As the understanding of gut microbiota has grown, its role in human health is gradually being emphasized. Gut microbiota coexists with humans as commensals, and it plays an important role in participating in host nutrient metabolism, maintaining the integrity of the intestinal barrier, and regulating the immune function. There is growing evidence that gut microbes have many complex physiological connections to multiple organs in the body. Under normal physiological circumstances, gut microbes maintain a dynamic balance. However, this balance may be disrupted by the occurrence of some diseases, manifested by changes in the structure or quantity of the gut microbiota. On the other hand, gut microbes can be potentially harmful when the gut micro-ecosystem undergoes abnormal changes, and dysbiosis of the gut microbes may affect the host health in many ways.¹¹ Small intestinal bacterial overgrowth (SIBO) is one of the most common forms of gut microbial dysbiosis, and studies have shown that it is associated with several diseases, such as irritable bowel syndrome, fatty liver, and metabolic syndrome.^{12–14} Gallbladder disease may be associated with SIBO. Abnormal gallbladder function can lead to an altered homeostasis of bile acids and a reduced antimicrobial effect, which may be one of the mechanisms of SIBO. In turn, SIBO might contribute to the development of gallbladder disease in a variety of ways. However, there is almost a gap in studies exploring the association between gallbladder diseases and SIBO. The purpose of this study was to investigate the prevalence of SIBO in patients with GBPs and to explore whether there is an association between these two conditions.

Materials and Methods

Study Design and Patients

From June 2021 to December 2021, patients with gastrointestinal discomfort (including abdominal pain, bloating, belching, dyspepsia, constipation, diarrhea, nausea and loss of appetite) from the Sixth Medical Center of the PLA General Hospital were enrolled in this study. The lactulose hydrogen-methane breath test was used to diagnose SIBO. All patients had an abdominal ultrasound as well as laboratory tests on the same day that they had the breath test. Patients were divided into GBPs group and control group according to whether GBPs were found under ultrasound. This study was conducted in accordance with the Declaration of Helsinki and approved by the Ethics Committee of the Sixth Medical Center of PLA General Hospital. Written informed consent was obtained from all subjects.

Inclusion and Exclusion Criteria

Inclusion criteria were patients aged 18 years or older who underwent a lactulose hydrogen-methane breath test to assess SIBO. Exclusion criteria were patients who 1) had taken antibiotics, H₂ receptor antagonists, proton pump inhibitors, probiotics, or medications that affect gastrointestinal motility within the last month; 2) had undergone vagotomy; 3) had a history of gastrointestinal surgery; 4) had a colonoscopy, barium enema, or any other test with a bowel preparation within one week; 5) had postprandial hypoglycemia; 6) were diagnosed with irritable bowel syndrome, inflammatory bowel disease, or chronic pancreatitis.

Demographic, Clinical and Laboratory Data

Clinical data were recorded including age, sex, height, weight, blood pressure, smoking, alcohol consumption, past medical history and medication history. Smoking was defined as smoking one cigarette per day for at least half a year, and drinking was defined as drinking at least once a week. Laboratory test data including fasting glucose, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, triglycerides, total cholesterol, total bile acids, albumin, alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, direct bilirubin, total bilirubin, and γ -glutamyl transpeptidase were also collected for each patient. Metabolic syndrome (MS) was defined according to the National Cholesterol Education Program Adult Treatment Panel III.¹⁵

Lactulose Hydrogen-Methane Breath Test

Each subject underwent a lactulose hydrogen-methane breath test, which was performed with reference to the North American Consensus.¹⁶ To improve the accuracy of the test, patients were required to strictly adhere to the following conditions: (1) avoid using antibiotics 4 weeks before the breath test; (2) fast for 8–12 hours before the breath test; (3)

avoid consuming fermentable foods such as complex carbohydrates (milk, buckwheat, beans, oatmeal, sweet potatoes, corn, etc.) the day before the breath test; (4) avoid smoking on the day of the breath test (burning tobacco can produce large amounts of hydrogen gas); and (5) limit strenuous activity during the test.

The lactulose hydrogen-methane breath test apparatus (QuinTron, QuinTron Instrument Company, USA) was used to first measure the patients' fasting H₂ and CH₄ values, and then the patients were instructed to take 10 g of lactulose with one cup of water. Exhaled hydrogen and methane levels were measured every 30 minutes for a total time of 210 minutes. The criteria for a positive diagnosis of SIBO were as follows: 1) an increase in hydrogen level ≥ 20 ppm from baseline within 90 minutes; and 2) a methane level ≥ 10 ppm during the test.

Ultrasonographic Examination

The subjects underwent an abdominal ultrasound examination in the fasting state, and a GBP was defined as a strongly or moderately echogenic nodule protruding from the gallbladder wall into the lumen, which did not move with body position and was not accompanied by a posterior acoustic shadow.³ The diagnosis of fatty liver was based on the Asia-Pacific Guidelines (diffusely enhanced echogenicity liver with liver echogenicity higher than kidney or spleen, vascular blurring, and deep beam attenuation).¹⁷ All procedures and diagnostics were performed by experienced ultrasound physicians who were blinded to the clinical and laboratory information of the subjects.

Statistical Analysis

SPSS version 26.0 (IBM, Armonk, NY, United States) was used for statistical analysis. Continuous variables were expressed as means \pm standard deviations, and categorical variables were expressed as frequencies and percentages. Student's *t*-test, chi-square test and Fisher's exact test were used to analyze differences between groups. Multivariable logistic regression was performed to identify the factors associated with GBPs and solitary polyps. The results of logistic analysis were expressed as the odds ratios (ORs) and 95% confidence intervals (95% CIs). P values < 0.05 were considered indicative of statistical significance.

Results

Among the 335 patients initially recruited, 18 patients met the exclusion criteria. Twenty patients were also ruled out due to a previous cholecystectomy (Figure 1). Eventually, a total of 297 subjects were included in this study (mean age, 56 years; range, 25–86 years), consisting of 60 patients with GBPs and 237 controls.

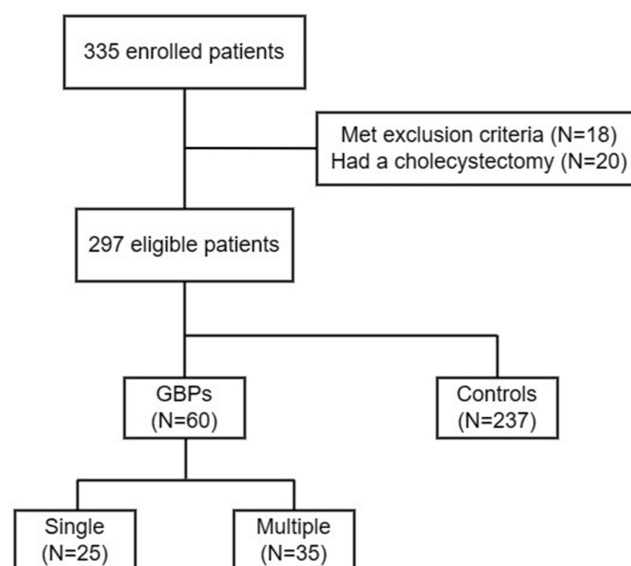

Figure 1 Flow chart.

Table 1 shows the characteristics of the GBPs group and the control group. SIBO was found in 30/60 patients with GBPs compared to 73/237 without GBPs (50.0% vs 30.8%, $p<0.01$; Figure 2). The mean age of the GBPs group was 54.9 years, including 46 males and 14 females, and the prevalence of GBPs was significantly higher in males than in females (25.6% vs 11.8%, $p<0.01$). The GBPs group had higher BMI ($p<0.01$), blood pressure values ($p<0.05$), and prevalence of fatty liver ($p<0.01$) and metabolic syndrome ($p<0.05$) than the control group. There were no significant differences in age, smoking, alcohol consumption and prevalence of gallstones between the GBPs and the control group. In addition, in terms of laboratory data, the fasting glucose levels were higher in the GBPs group ($p<0.05$), but the HDL-C levels were lower in the GBPs group than in the control group ($p<0.01$), and there were no statistical differences between the two groups on other laboratory data.

The GBPs group was divided into two groups including single and multiple polyp groups. The characteristics of patients with single polyps and multiple polyps were compared in Table 2. The prevalence of SIBO ($p<0.01$) and gallstones ($p<0.05$) were higher in the group with single polyps than those with multiple polyps. The fasting glucose values were higher in the single polyp group ($p<0.01$).

Multivariate regression analysis showed that male (OR=2.26, 95% CI=1.12–4.57, $p=0.023$), SIBO (OR=3.21, 95% CI=1.69–6.11, $p<0.001$), fatty liver (OR=2.91, 95% CI= 1.50–5.64, $p=0.002$) and BMI (OR=1.13, 95% CI=1.01–1.26, $p=0.035$) were independently associated with GBPs (Table 3). And fasting glucose (OR=3.04, 95% CI=1.27–7.28, $p=0.013$) and SIBO (OR=5.11, 95% CI=1.42–18.36, $p=0.012$) were independently associated with solitary polyps (Table 4).

Table 1 Univariate Comparison Between the GBPs and Control Groups

	Overall (n=297)	GBPs Group (n=60)	Control Group (n=237)	P-value

≥25	1.17	0.40–3.43	0.771
p for interaction			0.218

Discussion

GBP is one of the most common gallbladder diseases, and its detection rate is increasing with the widely available imaging examinations. The risk factors associated with GBPs remain unclear, previous studies have suggested that the formation of GBPs is associated with several factors, such as male sex, BMI, fatty liver and metabolic syndrome. Gut microbiota is the largest micro-ecosystem in the human body and it plays an important role in regulating metabolism and maintaining the health of the body. SIBO is one of the most common forms of gut microbiota disorders.¹⁸ A bacterial colony count of more than 10^3 CFU/mL in small intestinal aspirates is considered the criteria for the diagnosis of SIBO,¹⁴ but this traditional diagnostic method is complex and painful for patients. The hydrogen-methane breath test has an acceptable level of accuracy, is simple and noninvasive, and is now widely used to diagnose SIBO in clinical practice.

Increasing evidence reveals the role of SIBO in digestive diseases, however, the association between SIBO and gallbladder disease has not been fully investigated. To the best of our knowledge, the present study is the first to assess the association between GBPs and SIBO. We investigated the prevalence of SIBO in patients with GBPs and explored the association between these two conditions. The results showed a high prevalence of SIBO in patients with GBPs, and this association persisted after adjusting for potential confounders by multivariate regression analysis. In subgroup analysis, we found that the association between GBPs and SIBO was stronger in females than in males, although the reasons for this need to be further explored.

The pathogenesis of GBPs is complex and may involve a variety of factors, such as abnormal cholesterol metabolism and chronic inflammation. Excess cholesterol deposition on the gallbladder mucosa is one of the causes of the formation of GBPs, which can also promote gallbladder mucosal hyperplasia and impair the contractility of the gallbladder. Considering the antimicrobial properties of bile, the impaired gallbladder motility may contribute to the development of SIBO. In turn, SIBO can reduce the absorption of fat-soluble vitamins, such as vitamin D,¹⁹ and research has shown that vitamin D deficiency may further aggravate the cholestasis,²⁰ thus starting a vicious cycle. In addition, the formation of GBPs may be associated with a disturbance of the bile acid pool²¹, which is common in SIBO. Previous studies have found that compared to SIBO-negative patients, the levels of unconjugated bile acids were higher in SIBO-positive patients.^{22,23} The possible explanation for that is the increased number of colon-specific bacteria in the small intestine under the condition of SIBO, which can lead to an increase in the deconjugation of bile acids. However, further studies are needed to elucidate the specific mechanisms of the association between SIBO and GBPs.

In the present study, male and BMI were independently associated with GBPs. And higher BMI appears to be related to SIBO.²⁴ Previous studies have shown that distal small intestinal transit is slowed in obesity because of the presence of leptin resistance,²⁵ and the reduced clearance capacity of the small intestine due to motility disorders is an important trigger for SIBO. The present study suggests that fatty liver is closely associated with GBPs, which is consistent with previous studies.^{9,26} The study by Ahn et al⁹ found a dose-dependent relationship between fatty liver and increased risk of GBPs, and that fatty liver may be a risk factor not only for cholesterol polyps but also for adenomatous gallbladder polyps. The association between SIBO and fatty liver has been reported several times. A meta-analysis including 10 studies showed that patients with SIBO had a significantly increased risk of developing fatty liver.²⁷ The exact mechanism of the association between SIBO and fatty liver is still being explored, and it is now generally accepted that it may be related to the impaired intestinal barrier and increased translocation of bacteria and bacterial by-products in patients with SIBO.²⁸ SIBO-positive patients have been shown to have a higher level of endotoxin and significantly increased expression of CD14, NF- κ B and TLR4 compared to SIBO-negative patients.²⁹ Notably, the production of various inflammatory cytokines can directly participate in the non-alcoholic steatohepatitis (NASH).²⁹ In addition, this chronic inflammatory state can induce the insulin resistance, which is one of the important mechanisms of fatty liver.³⁰

In the univariate analysis, we found that the prevalence of metabolic syndrome were higher in the GBPs group than in the control group, but this difference was no longer significant in the multivariate analysis, which we consider might be related to the small sample size. Previous studies have shown that metabolic syndrome is a risk factor for GBPs.^{31,32} Metabolic syndrome is a complex multifactorial metabolic disease that refers to a pathological state in which the body's substances such as proteins, fats and carbohydrates are metabolically disordered. Studies suggested that there was an increased inflammatory response in metabolic syndrome patients, which may be associated with altered gut microbiota and increased penetration of impaired intestinal membranes by bacterial components.³³ SIBO has been reported to be associated with the metabolic syndrome and its components. Fialho et al³⁴ compared the prevalence of metabolic syndrome and its components in SIBO-positive versus SIBO-negative patients, they found that the prevalence of metabolic syndrome was higher in the SIBO-positive group than in the SIBO-negative group, and this association persisted after adjusting for confounding factors.

In the current study, reduced HDL-C was also a related factor for GBPs at univariate analysis, whereas not at multivariate analysis. Whether reduced HDL-C is a risk factor for GBPs is controversial. A study by Yang et al³⁵ found that HDL-C was one of the risk factors for GBPs, and their results showed that subjects with lower HDL-C levels had a 3.346 times higher risk for having GBPs than control subjects. However, the study from Zheng et al³⁶ found significant

differences in LDL and cholesterol (TC) levels between the GBPs and control groups, and no differences in HDL and triglyceride (TG) levels.

We also found that SIBO and fasting glucose were associated with solitary polyps in this study (Table 4), but the mechanism of this association was not clear. Several previous studies reported that compared to benign polyps, malignant polyps were often solitary,^{37–39} although this view remains controversial. A recent study by Terzioglu et al⁴⁰ also showed that isolated polyps were an independent predictor of neoplastic GBPs. However, for GBPs, it is difficult to make a definitive histological diagnosis except for postoperative pathological confirmation. Further prospective studies are needed to confirm whether SIBO is associated with the formation of neoplastic polyps or an increased risk of malignant transformation of the polyps.

There are still some limitations of this study. First, the breath test is not the gold standard for diagnosing SIBO, but it has an acceptable level of accuracy. Second, cross-sectional study prevents us from determining a causal link between SIBO and GBPs, and we could not ascertain the timing and sequence of the occurrence of SIBO and GBPs.

In conclusion, according to the above analysis, our study for the first time found an association between SIBO and GBPs, although this association may be a coincidental occurrence rather than a causal one. Further prospective studies are needed to verify these results and explain the exact mechanism. If confirmed, patients with GBPs, especially females, might benefit from the assessment of polyps and active control of their risk factors.

International Journal of General Medicine

Dovepress

Publish your work in this journal

The International Journal of General Medicine is an international, peer-reviewed open-access journal that focuses on general and internal medicine, pathogenesis, epidemiology, diagnosis, monitoring and treatment protocols. The journal is characterized by the rapid reporting of reviews, original research and clinical studies across all disease areas. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
