Abstract: Very low-calorie diets (VLCDs) are an effective means by which to induce clinically significant weight loss. However, their acceptance by health care practitioners and the public is generally lower than that for other nonsurgical weight loss methods. Whilst there is currently little evidence to suggest they have any detrimental effect on hepatic and renal health, data assessing these factors remain limited. We carried out a systematic review of the literature on randomized controlled trials that had a VLCD component and that reported outcomes for hepatic and renal health, published between January 1980 and December 2012. Cochrane criteria were followed, and eight out of 196 potential articles met the inclusion criteria. A total of 548 participants were recruited across the eight studies. All eight studies reported significant weight loss following the VLCD. Changes in hepatic and renal outcomes were variable but generally led to either no change or improvements in either of these. Due to the heterogeneity in the quality and methodology of the studies included, the effect of VLCDs on hepatic and renal outcomes remains unclear at this stage. Further standardized research is therefore required to fully assess the impact of VLCDs on these outcome measures, to better guide clinical practice.

Keywords: obesity, liver, kidney, weight loss, health

Introduction

The prevalence of overweight and obesity is increasing globally, and effective weight loss treatment is of great importance from both a health and socioeconomic perspective.¹ Very low-calorie diets (VLCDs) are an effective means by which to induce a clinically significant weight loss.² However, their acceptance by health care practitioners and the public, in general, is much lower than that for other nonsurgical weight loss methods. This is likely to be due to the adverse effects of the nutritionally insufficient VLCDs that were popular in the 1970s, which resulted in a number of deaths due to vitamin and mineral deficiencies and consumption of poor quality or inadequate amounts of protein.^{3,4} The VLCDs of the past were, however, completely different from the nutritionally replete variants of modern day VLCDs, and despite the fact that fast weight loss, seen in followers of a VLCD, is still generally perceived as being unsafe, there is no convincing evidence to suggest that this is the case. Indeed, the European Food Safety Authority has approved a health claim with regards to the efficacy of VLCDs on weight loss, in a target population of obese adults.⁵

A VLCD is defined as a diet of <800 kcal/day,⁶ and there are many commercially available variants that provide energy intakes between 300–800 kcal/day.

There is sufficient evidence in the literature to ensure the safe use of VLCDs in healthy overweight and obese patients in the short term,^{7,8} however, there remains

Email ext.rolland1@rgu.ac.uk

limited evidence on the effects of VLCDs on specific disease groups over this same period of time. This is likely to, in part, be due to the strict protocols and monitoring that are advised with this type of dietary approach to weight loss. Although the evidence for the benefits of VLCDs is mounting in certain groups of individuals at higher cardiovascular risk, for example those with type 2 diabetes mellitus,^{9,10} there is little evidence of outcomes in patients with other obesity-related secondary diseases, such as nonalcoholic fatty liver disease (NAFLD). In a recent review, Mulholland et al,² investigating long-term (>12 months) randomized control trials of VLCD, identified only two reports of studies that evaluated effects on liver and kidney function.^{11,12} One paper¹¹ described that at 2 years follow up, there were no significant changes in liver transaminases. The other paper¹² reported both statistically and biologically significant improvements in both hepatic and renal health, including changes in alanine aminotransferase, alkaline phosphatase, γ -Glutamyl transferase, creatinine, estimated glomerular filtration rate (eGFR), and urea. The observed changes in liver enzymes indicated an improvement in hepatic steatosis and an improvement in the biochemical markers associated with renal and hepatic pathology.

Furthermore, a recent study by Lim et al¹³ reported that in patients with type 2 diabetes mellitus who followed a VLCD, the resulting acute negative energy balance reversed the type 2 diabetes mellitus by normalizing both insulin sensitivity and beta cell function. The authors suggested this result was due to the reduction of fat in the liver and pancreas. These results are in keeping with our previous findings, which demonstrated improvements in liver enzymes following a VLCD.¹²

Whilst there is currently little evidence to suggest VLCDs cause any detriment to liver or kidney health, data assessing these factors remain limited. Thus, we aimed to carry out a systematic review of the literature and of studies investigating a VLCD and reporting outcomes for liver and kidney health, published between January 1980 and December 2012.

Methods

The protocol used for this systematic review follows the methods recommended by the Cochrane Collaboration.¹⁴ Further details of the approach are described below.

Inclusion criteria

This review was intended to assess the literature in this field. Studies from January 1980 to December 2012 were evaluated. Studies prior to 1980 were not included, due to health concerns associated with the formulations of the VLCDs in the

1970s.^{3,4} Only investigations of adult (18 years and over) participants with a mean or median body mass index (BMI) of ≥ 28 kg/m² were included, and only randomized, controlled trials with a VLCD component were evaluated. Variations in the duration of the intervention which were aimed at achieving weight loss (ie, active weight loss prior to weight maintenance approaches) were recorded and accounted for, where possible.

Types of interventions

The focus of this review was to examine the effect of VLCDs on hepatic and renal outcomes. The types of dietary interventions evaluated were VLCDs (also known as very low-energy diets), defined as a dietary intake of 800 kcal/day or less.

Outcome measures

Weight loss was the main outcome assessed in the studies included in the review. With regard to hepatic or renal status, the following outcomes were also included:

- Liver enzymes (alanine aminotransferase [ALT], alkaline phosphatase [ALKP], aspartate transaminase [AST], gamma-glutamyl transpeptidase [GGT], and albumin)
- Electrolytes and markers of urea and kidney function (sodium, potassium, chloride, creatinine, and eGFR)
- NAFLD.

Search strategy for the identification of included studies

This systematic review was restricted to studies where the full study report was available. A search strategy on MEDLINE was applied to identify as many as possible of the studies evaluating dietary interventions using VLCDs and relevant to hepatic and renal status. The search strategy incorporated the terms “very low calorie diet” and “very low energy diet.” Authors were contacted for further details of their trials and the reference lists of included studies and reviews were also searched.

Quality assessment of studies

The protocol used for the quality assessment followed the methods recommended by Avenell et al.¹⁵ The studies were classified as having either a low risk of bias (A), an unclear risk of bias (B), or a high risk of bias (C). The subset “I” suggested that a description was provided, while the subset “II” suggested that no description was provided.

Full copies of studies were assessed by two researchers, for methodological quality. The researchers were not blinded to the author, journal, or institution. Differences of opinion were resolved by discussion. The trial quality was assessed

and included a consideration of whether or not the analysis was undertaken on an intention-to-treat basis.

Identified studies

A total of eight out of 196 articles met the inclusion criteria and were included in the systematic review. The reasons for the exclusion of studies are summarized in Figure 1.

Results

Study characteristics

A total of 548 participants were recruited across the eight studies included in this systematic review. There was a large amount of heterogeneity in the study design for the papers meeting the inclusion criteria. The studies included ranged from 8 weeks¹⁶ to 2 years¹¹ in duration. The duration of the VLCDs ranged from 25 days¹¹ to 9 months.¹² In the follow-up phase, different studies incorporated aspects of behavior modification,¹¹ reduced calorie intake,¹⁷⁻¹⁹ or medication (acarbose) (Table 1).²⁰

All of the studies were designed to reduce weight or prevent weight gain and also examined hepatic and renal outcomes. The results of all the studies are summarized in Table 1.

Quality assessment

Table 2 displays the quality assessment of the reported studies. All of the studies were randomized, but the allocation

description was generally not provided, with the exception of one paper,²¹ in which the method of concealment had a real chance of disclosure of assignment prior to formal trial entry. Four studies^{11,18-20} clearly stated the numbers and reasons for withdrawal from the study, while two studies^{12,21} only provided the numbers of withdrawals, and two studies^{16,17} made no mention of dropouts. Three studies analyzed the data with the intention to treat,^{12,20,21} while three^{16,17,19} may also have done so, but the methods of analysis were unclear, and the final two studies^{11,18} presented data for completers only. Participants as well as health care providers were blinded to the treatment in two studies (of a test emulsion,¹⁸ and acarbose,²⁰ respectively); participants were not blinded in the other six studies, and it was unclear whether the health care providers or the outcome assessors were blinded to treatment status.

Weight change

All eight of the studies resulted in significant weight loss following the VLCD period (Table 2). Where weight change was reported after a follow-up period, the implementation of any of a reduced-calorie diet,¹⁷ regular support through intensive or less intensive behavior modification therapy,¹¹ meal replacement once a day,¹⁸ or ongoing use of VLCD¹² resulted in the maintenance of significant weight loss compared with baseline. Although no values for weight change were provided, Hauner et al²⁰ stated that the use of acarbose resulted in individuals remaining at a stable weight for the weeks following the VLCD (Table 2).

Hepatic outcomes

Table 3 displays the results for different hepatic outcomes reported in three of the studies. Arai et al¹⁶ observed an improvement in AST and ALT following the VLCD. Rolland et al¹² also reported an improvement in ALT as well as in ALKP, GGT, and albumin following the VLCD period. Melin et al¹¹ provided baseline values but only anecdotally reported (ie, no values were presented) that there were no changes in the liver transaminases.

Two other studies reported anecdotal results of changes in hepatic outcomes. Olsson et al¹⁸ reported that ALT levels increased significantly during the weight-reduction phase but were normalized during the 12-week weight maintenance phase, whereas Hauner et al²⁰ reported that no changes were observed in the serum transaminases in participants undergoing a VLCD followed by the use of acarbose.

Only one study investigated the effect of VLCDs on NAFLD. In the study by Lin et al,²¹ 41 participants with NAFLD were placed on a 450 kcal/day VLCD for 12 weeks.

Figure 1 Summary of the literature search.

Abbreviations: RCT, randomized controlled trial; VLCD, very low-calorie diet.

Table 1 Summary of studies included in the review

Author	N (males)	Study	Mean BMI (kg/m ²)
Arai et al ¹⁶	45 (12)	RCT in which patients undertook either 1. Supplemental LCD (3515–5021 kJ/d with use of 2–3 packages of Optifast 70 and 2678–3682 kJ of conventional balanced meals consisting of a mixture of 88 g P, 30–80 g CHO, 4–9 g F) or 2. VLCD where participants used 5 packages of Optifast 70 (daily energy intake of 1757 kJ, 70 g protein, 30 g CHO, 2 g F)	SLCD: 31.9 (4.4) VLCD: 32.9 (6.1)
Doherty et al ¹⁷	26 (0)	RCT in which patients received either 1. Control: diet of their choosing throughout the 45 weeks (control); 2. VLCD: 1 week of a 1200 kcal/d BDD and a 420 kcal/d liquid diet for weeks 2–17. Patients were realimented during weeks 18–24 by increasing the daily caloric intake by extra ~150 kcal for each week of realimentation until reaching ~1150 kcal/d at week 24. Patients were instructed to consume a balanced diet providing 1200–1500 kcal/d for the remainder of the treatment (weeks 26–45) 3. BDD + exercise: consume a BDD providing 1000–1500 kcal/d (15%–20% protein; 50%–55% CHO, 30% fat) for 45 weeks. Instructed (at week 8) to begin a program of aerobic activity (mostly consisting of walking). Initially 10–20 minutes two to three times per week. By end of study, they reported exercising for 20–40 minutes three to five times per week	Control: 33.4 (2) VLCD: 40.4 (2) BDD: 36.5 (2)
Hauner et al ²⁰	110 (22)	RCT in which patients underwent a pretreatment phase of VLCD/LCD (700–1000 kcal/d) to achieve a weight loss of at least 2–3 BMI units. Afterwards, participants were asked to maintain an individually tailored weight-maintaining diet and were either prescribed a placebo or acarbose (treatment started with 50 mg once/day and titrated up to a maximum of 100 mg tid at weekly intervals)	Placebo: 34.8 (2.2) Acarbose: 34.7 (2.3)
Lin et al ²¹	132 (43)	RCT in which patients undertook a 2-week introduction phase during which they consumed a 1200 kcal/d diet. This was followed by a 450 kcal/d VLCD or an 800 kcal/d VLCD for 10 weeks	VLCD 450: 34.4 (3.5) VLCD 800: 34.1 (3.9)
Melin et al ¹¹	43 (4)	RCT in which patients undertook a 25-day VLCD followed by hypocaloric diet. Patients were divided into two groups Group 1: intensive behavior modification therapy every fortnight during the first year and six meetings in the second year Group 2: planned meetings every third month	Group 1: 35.6 (4.5) Group 2: 35.2 (4.6)
Olsson et al ¹⁸	43 (0)	RCT in which patients were assigned to a 6-week VLCD to achieve at least a 5% reduction in body weight, after which they resumed habitual eating patterns except for lunch, which was replaced by Nutrilett® Intensive meal (111 kcal) mixed with a control or a test emulsion	Control: 28.3 (1.6) Emulsion: 28.2 (1.4)
Rolland et al ¹²	120 (11)	RCT where patients were assigned to a 600 calorie-deficit diet for 3 months. Those who did not achieve a 5% weight loss were randomized to either: LCHP or VLCD for the following 9 months	LCHP: 41.6 (4.8) VLCD: 46.0 (7.0)
Ryttig and Rössner ¹⁹	60 (11)	RCT in which patients were assigned to 12 weeks of VLCD followed by a gradual increase of normal food during 1 week. After transition, patients were assigned to either: Group 1: normal, well-balanced hypocaloric diet containing 1600 kcal/d, of which 220 kcal was provided by two sachets of the Cambridge diet Group 2: normal, well-balanced hypocaloric diet containing 1600 kcal/d of solid food only	Group 1: 38.0 (4.9) Group 2: 40.3 (6.0)

Notes: Values are reported as mean (standard deviations), unless stated otherwise. Δ represents a change. ^aP < 0.05 from baseline; ^bP < 0.001 from baseline; ^cP < 0.0001 from baseline; ^dP < 0.05 between groups; ^eP < 0.001 between groups.

Abbreviations: BDD, balanced deficient diet; BMI, body mass index; CHO, carbohydrate; F, fat; kJ/d, kilojoules per day; LCD, low-calorie diet; LCHP, low carbohydrate high protein; P, protein; RCT, randomized controlled trial; SE, standard error; SLCD, supplemental low-calorie diet; tid, three times daily; VLCD, very low-calorie diet.

In this group, a 41.5% improvement rate in NAFLD was reported, where five of the 41 participants no longer had NAFLD, and others had improvements in severity; however, of the five participants in this group who did not have NAFLD at the beginning of the intervention, two had developed NAFLD by the end of the intervention. Lin et al²¹ also had participants on an 800 kcal/d VLCD. In this latter group, they observed a 50% improvement

rate, where of the 42 participants who initially presented with NAFLD, ten no longer had NAFLD, and of the five participants who did not have NAFLD at baseline, none developed it.

Renal outcomes

Table 4 displays the results of the renal outcomes from the only paper¹² that provided values for changes in renal function.

Inclusion criteria	Duration of VLCD	Duration of follow up	Weight (kg) at baseline	Weight (kg) at the end of the VLCD period	Weight (kg) at the end of the follow up period
Overweight adult men and women	8 weeks	–	SLCD: 81.5 (14.0) VLCD: 82.0 (20.0)	SLCD: 76.3 (14.7) ^a VLCD: 73.0 (16.3) ^a	–
Obese women	15 weeks	29 weeks	Control: 94.7 (5.0) VLCD: 111.2 (5.0) BDD + exercise: 102.8 (6)	Control: Δ 2.7 (1.2) VLCD: Δ -21.3 (2.1) ^{a,d} BDD + exercise: Δ -10.3 (2.7) ^{a,d}	Control: Δ 3.9 (2.3) VLCD: Δ -22.4 (3.4) ^{a,d} BDD + exercise: Δ -14.5 (5.5) ^{a,d}
Weight stable obese subject with BMI 32–38 kg/m ²	10–16 weeks	26 weeks	Placebo: 97.8 (13.0) Acarbose: 97.7 (13.5)	No values	Placebo: Δ 0.6 kg Acarbose: weight stable (no values)
Obese (BMI \geq 30 kg/m ²) Taiwanese between the ages of 18–65 years	10 weeks	–	450 kcal/d: 92.5 (14.1) 800 kcal/d: 92.1 (15.6)	450 kcal/d: Δ -8.37 (0.70) ^b 800 kcal/d: Δ -8.42 (0.70) ^b	–
Men and women; 24–60 years old; BMI 35 kg/m ² (29–48)	25 days	2 years	Group 1: 99.8 (5.5) Group 2: 93.4 (4.1)	Group 1: Δ -8.3 (0.64) ^b Group 2: Δ -10.0 (0.71) ^b	Group 1: Δ -6.8 (1.4) ^a Group 2: Δ -8.6 (1.6) ^a
Female; 18–60 years; BMI 26–31 kg/m ²	6 weeks	12 weeks	Control: 79.0 (8.3) Test emulsion: 79.7 (6.1)	Control: 71.5 (7.1) ^a Test emulsion: 73.0 (5.3) ^a	Control: 70.2 (6.9) ^a emulsion: 72.0 (5.6) ^a
Men and women; > 18 years old; BMI \geq 35 kg/m ²	6.9 months (4–9 months)	–	LCHP: 110.4 (12.2) VLCD: 129.6 (23.0)	–	LCHP: 109.1 (14.6) VLCD: 98.0 (20.3) ^{c,e}
Obese men and women (BMI \geq 30 kg/m ²), between 19–65 years, with stable body weight within the previous 2 months (less than 3 kg fluctuation)	12 weeks	52 weeks	Solid food: 120.1 (22.5) ^e Meal replacement: 108.1 (15.8)	Solid food: 97.6 (19.1) ^{a,d} Meal replacement: 85.7 (14.7) ^a	No significant change during the weight maintenance period between the groups (no values provided)

The results demonstrated an improvement in creatinine, urea, and eGFR levels in response to a VLCD.

Two other studies reported anecdotal outcomes for renal function. Doherty et al¹⁷ reported that there were no significant changes in potassium, sodium, or chloride observed at 45 weeks in response to a VLCD followed by a balanced deficit diet. Similarly, Rytting and Rössner¹⁹ reported that there were no significant changes in serum electrolytes

(sodium, potassium) at the end of the 12 weeks of VLCD or during the weight maintenance period, between the two groups (balanced hypocaloric diet with or without a meal replacement component).

Discussion

As expected from previous studies, the VLCD interventions resulted in significant weight loss. The changes in hepatic and

renal outcomes resulting from the weight loss achieved using the VLCDs were variable, but generally, there was either no change or an improvement in hepatic and renal health. This may be due to the fact that these studies measuring kidney and liver outcomes only included adults with normal kidney and liver function, with the exception of NAFLD.

The outcomes in terms of hepatic function were improved in some studies, remained the same in others, and initially increased during the VLCD phase but normalized thereafter in one study. The inconsistencies between these studies are likely to be due to a combination of things, including the different lengths of treatment, different sampling times, as well as different weight maintenance approaches. However, these studies certainly did not demonstrate any negative outcomes for hepatic health in response to a VLCD and subsequent follow up. On the contrary, when looking at the outcomes for NAFLD, the effect of the weight loss achieved by the VLCD resulted in important improvements in NAFLD, most likely due to the associated decrease in visceral adiposity.²²

These results are supported by our earlier findings¹² and suggestion that changes in liver enzymes may indicate an improvement in hepatic steatosis. Several other studies have also suggested beneficial effects of weight loss on liver size and adiposity. Colles et al²³ observed that during a 12-week VLCD, most of the reduction in liver size occurred in the first 2 weeks of weight loss, likely due to the depletion of liver glycogen and bound water (caused by the low carbohydrate content of the diet).²⁴ Favorable changes were also observed in a range of biochemical and clinical tests (significant decreases in ALKP, bilirubin, ALT, and GGT). Andersen et al²⁵ investigated the effects of weight loss induced by a VLCD on liver morphology and function in morbidly obese but otherwise healthy individuals. They observed a marked improvement in hepatic health, which correlated with the reduction of weight. However, they also observed that 24% of the patients developed a slight portal inflammation as well as, in 12% of patients, a slight portal fibrosis. They did not find predictors (morphological or biochemical) for

these changes and hypothesized that a fast mobilization of intracellular triacylglycerols and subsequent secretion of fatty acids had induced a portal inflammation, which in turn, led to the fibrosis. They proposed that a rapid mobilization of intra- and extrahepatic fat stores may present a hepatotoxic factor common to all weight loss treatments that induce rapid weight loss. Based on their observations, they postulated that to avoid the development of portal fibrosis during treatment with VLCD, a weight loss slower than 1.6 kg/week should be recommended.

The issue of the development of fibrosis in the study by Andersen et al²⁵ should not be confused with the development of fibrosis observed in individuals following bariatric surgery, another approach that induces rapid weight loss. Several studies have reported improvements in liver biochemical and histological outcomes following bariatric surgery,^{26–28} but some authors have expressed concern that rapid weight loss may be a causative factor in the occurrence of fibrosis that was observed.^{27–29} However, as Kral et al²⁸ suggest, this may be due to a decreased serum albumin and poorly managed diarrhea, which are two known potential side effects of certain types of bariatric surgery. The problems with hepatic fibrosis are well known³⁰ and are probably not related to the rate of weight loss but rather, to surgically induced short bowel syndrome. Certainly, the issue of fibrosis did not figure in the clinical trials highlighted in this systematic review, and such situations are not generally associated with the use of low-calorie diet or VLCD interventions.

Limited information was available regarding the response of renal function to the weight loss induced by VLCD. Nevertheless, the current data suggest either an improvement or no change in response to weight loss induced by a VLCD followed by a weight maintenance period.

Previously, we suggested that improvements in renal function during a VLCD are possible, due to the associated increase in fluid intake and/or reduction in creatine intake.¹²

Obesity-related glomerular disease was first identified by Weisinger et al³¹ in the 1970s, and the prevalence of obesity-related glomerulopathy has been increasing as a consequence of the obesity epidemic.³² It has been suggested that reducing the glomerular hyperfiltration observed in the obese may provide a way to prevent or delay the development of renal disease in these individuals.³³ Indeed, Chagnac et al³³ demonstrated improvements in GFR following weight loss induced by a gastroplasty. This finding is supported by the review by Navaneethan et al,³⁴ in which the researchers reported that in patients with chronic kidney disease, bariatric surgery was associated with a decrease in BMI, with resultant normalization of glomerular hyperfiltration; however, they also stated that it remains to be clarified whether this normalization can result in long-term renal benefits. Previously, we reported an improvement in eGFR following the VLCD.¹² The use of eGFR, however, is a poor indicator of improved renal function in this case – as a direct result of the use of VLCDs, the intake of creatine drops dramatically, and hence, the serum creatinine also drops, and this may give a false impression of improved renal function. Also, the use of eGFR significantly underestimates measured kidney function with obesity, and measuring changes in eGFR when body surface area is also changing is problematic.³⁵

In addition, the use of eGFR has not been validated in patients with normal kidney function.

Strengths and limitations

The main limitation of this review is the small number of studies included as well as the lack of data presented in many

of the studies. In addition, the heterogeneity of the studies in terms of study quality, treatment duration, outcomes measured, and time points rendered it impossible to carry out a meta-analysis. It is also important to highlight that only one study¹⁶ reported hepatic outcomes, and none reported renal outcomes immediately post-VLCD (or during active VLCD) compared with follow up (long after the VLCD was completed).

Finally, in assessing kidney function outcomes, it would have been beneficial to have information about renal blood flow, arterial pressure, and albuminuria.

Conclusion

There are currently no effective treatments for NAFLD other than weight reduction and lifestyle modification.^{36,37} The effect of VLCDs on hepatic and renal outcomes remains unclear at this stage. There have been a number of improvements observed in terms of hepatic and renal outcomes; however, there may be some concern about the onset of fibrosis in some individuals, although no evidence for this was observed in the current systematic review. Renal outcomes seem little affected by VLCDs; however, the studies measuring kidney function included only adults with normal kidney function, and the results cannot be extrapolated to those with any degree of kidney dysfunction. At this stage, further standardized research is required to fully assess the impact of VLCDs on hepatic and renal health and to better advise clinical practice.

Acknowledgments

This research was funded by LighterLife Ltd, UK.

Disclosure

CR has received lecture honoraria and has attended national/international meetings as a guest of LighterLife Ltd, UK. CR and JB have been involved with other companies with an interest in obesity. JB and KLJ are employed by LighterLife Ltd, UK. The authors report no other conflicts of interest.

Diabetes, Metabolic Syndrome and Obesity: Targets and Therapy

Dovepress

Publish your work in this journal

Diabetes, Metabolic Syndrome and Obesity: Targets and Therapy is an international, peer-reviewed open-access journal committed to the rapid publication of the latest laboratory and clinical findings in the fields of diabetes, metabolic syndrome and obesity research. Original research, review, case reports, hypothesis formation, expert

opinion and commentaries are all considered for publication. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
