Abstract: Controlled and contactless movements of magnetic nanoparticles are crucial for fundamental biotechnological and clinical research (eg, cell manipulation and sorting, hyperthermia, and magnetic drug targeting). However, the key technological question, how to generate suitable magnetic fields on various length scales (μm – m), is still unsolved. Here, we present a system of permanent magnets which allows for steering of iron oxide nanoparticles (SPIONs) on arbitrary trajectories observable by microscopy. The movement of the particles is simply controlled by an almost force-free rotation of cylindrical arrangements of permanent magnets. The same instrument can be used to move suspended cells loaded with SPIONs along with predetermined directions. Surprisingly, it also allows for controlled movements of intracellular compartments inside of individual cells. The exclusive use of permanent magnets simplifies scaled up versions for animals or even humans, which would open the door for remotely controlled in vivo guidance of nanoparticles or micro-robots.

Keywords: permanent magnets, Halbach, super-paramagnetic, steering, targeting

Introduction

One of the most auspicious promises of nanomedicine is to replace the current systemic treatment of local diseases to significantly reduce the associated side effects, as large amounts of the drug affect healthy cells or remain mainly in organs, such as liver, kidney, lung.¹ One way to focus treatment is the application of drugs or nanoparticles functionalized with antibodies or capture proteins that specifically bind to diseased cells or tissues.^{2,3} However, even these approaches are not free of side effects, as a large amount is still captured in non-target organs, tissues or by the reticuloendothelial system.^{4,5} A more site-specific application of pharmaceutical drugs or particles is desirable and urgently needed and could be realized by magnetic drug targeting (MDT). In addition to MDT, where particles must be directed to a specific location, there are other applications where cell guidance is required.⁶ As in the migration and adhesion of cells during embryonic development, tissue formation and wound healing, the targeted guidance of cells is a prerequisite for many areas in regenerative medicine and tissue engineering. Magnetic force-based guidance of cells for separation, isolation, concentration, and patterning has become an important biotechnological tool for cell and tissue bioengineering with low adverse effects on cell viability.⁷ For example, the guidance of magnetically labelled cells enables the manipulation of cells in 2D and 3D cell cultures to form various structures, such as multilayer sheets and spheroids and enables the mimicking of tissue-specific in vivo structures.

Magnetic stem cell delivery is a promising approach for the treatment of neurodegenerative diseases, myocardial infarction, cartilage, bone or spinal cord injuries.^{8–11} The cell delivery could be realized by invasive magnetic implants or non-invasive external magnetic systems. However, the exact guiding to the lesion site is still a challenge and a clinical implementation has not yet been developed. Nevertheless, the vision remains to move nanoparticles and nanoparticle-loaded cells non-invasively along predetermined pathways in the human body via suitable magnetic fields. In order to engineer such a magnetic device, several principal and technical problems have to be hurdled.

A magnetic force is given by the gradient of the magnetic flux times the magnetic moment of the object.¹² However, Gauss's law dictates that a single flux gradient cannot exist in a source-free space and therefore it is difficult to have a bijective force direction. To generate a force that overcomes hydrodynamic friction and even blood flow, the flux gradient as well as the magnetic moment of nano-sized objects must be substantial. Therefore, ferro- or superparamagnetic materials (eg, iron oxides particles) are an obvious choice for the nano-sized objects.^{13,14} Tiny paramagnetic objects in a time-independent magnetic field align their magnetic moment along the local flux direction. Consequently, magnetic moment and magnetic flux have the same direction and the force always points in the direction of the highest flux (also known as Earnshaw's theorem). An everyday observation that magnets attract ferromagnetic objects (eg, paper clips) in the same way by their south or north pole. Hence, steering requires time-dependent magnet fields.¹⁵ Based on this reasoning, permanent magnets are not typically considered as useful flux sources for this application, although they offer some important advantages over electromagnets, in particular when the devices need to be scaled up. This is because electromagnets require enormous power for field generation and cooling. Furthermore, the time-dependence of a large coil is far from being linear, as the large inductance of big coils causes severe delays in discharging and charging, making rapid changes in control currents and thus magnetic fields difficult.¹⁶ Nonetheless, it has been demonstrated that permanent magnets can also be arranged in such a way that the direction and strength of both homogeneous and graded magnetic fields can be changed by simple mechanical rotation.^{17–19}

Materials and Methods

Reagents

Iron (II) chloride tetrahydrate ($\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$), hydroxylammonium chloride, and Eppendorf ultrafiltration tubes with a molecular weight cut-off (MWCO) of 3 kDa were purchased from Merck (Darmstadt, Germany). Iron reference standards 1 g/L were bought from Bernd Kraft GmbH (Duisburg, Germany). Iron (III) chloride hexahydrate ($\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$), dialysis tubes (Spectrapor 6, MWCO 8 kDa), sterile Rotilabo[®] syringe filters with cellulose mixed ester membranes were supplied by Roth (Karlsruhe, Germany). Spectra/Por[®] 6 dialysis tubing with an MWCO of 10 kDa and a diameter of 29 mm was purchased from Serva Electrophoresis (Heidelberg, Germany). DMEM was purchased from Biochrom (Berlin, Germany), L-glutamine from PAA Laboratories (Pasching, Austria). Endothelial Cell Growth Medium (ECGM) with supplements (C-22010, C-39215) was purchased from PromoCell (Heidelberg, Germany). Water used in all experiments was of ultrapure quality.

Synthesis of in situ-Coated Poly(Acrylic Acid-Co-Maleic Acid) SPIONs (SPION^{PAM})

Poly(acrylic acid-co-maleic acid)-coated superparamagnetic iron oxide nanoparticles (SPION^{PAM}) were synthesized using a previously reported protocol.^{20,21} Briefly, iron oxide nanoparticles were synthesized by coprecipitation of iron (II) and iron (III) at a stoichiometric ratio of 1:2 under argon atmosphere at 80 °C. After purification by dialysis, the particles were coated with PAM. The particles were thereby diluted in a 25% (w/v) solution of PAM to a total iron concentration of 5 g/L. The pH was adjusted to pH 6.5 using sodium hydroxide solution (5.0 N), and the suspension was stirred for 24 h. Excess polymer was removed by multiple centrifugations and resuspension in ultrapure water.

Iron Quantification

The total iron content was determined using an Agilent 4200 microwave plasma-atomic emission spectrometer (MP-AES, Agilent Technologies, Santa Clara, CA). Three different aliquots (50 μL) of the respective ferrofluid were dissolved in 50 μL nitric acid 65%, dissolved for 10 min at 95 °C and diluted with 450 μL H_2O . The iron content was then determined with MP-AES using a commercial iron solution as an external standard. The

calibration curve was prepared with iron concentrations ranging from 0.05 mg/L to 2.5 mg/L. If the coefficient of determination (R²) in this given range exceeded 0.999 we proceeded with the quantification of the samples.

Magnetic Susceptibility Measurements

As measure of the magnetizability, the magnetic susceptibility of the particles was determined using a commercial susceptometer (MS2G; Bartington[®] Instruments, Oxon, UK) and normalized to the iron content of the suspension. The magnetic susceptibility of Resovist[®] ($7.72 \cdot 10^{-3}$) and Rienso[®] ($1.49 \cdot 10^{-3}$) was analyzed as a reference.

Dynamic Light Scattering (DLS) and Zeta Potential Measurements

The hydrodynamic sizes and Zeta potentials in water and cell culture media were determined using a Malvern Zetasizer Nano ZS (Malvern Instruments, Worcestershire, England). The particles were diluted to a total iron concentration of 30 µg/mL with ultrapure water and measured in triplicates at 25 °C.

Commercially Available Magnetic Nanoparticles

Magnetic nanoparticles were purchased from Micromod (Germany) labelled with a red fluorescent dye (Ex: 552 nm/Em: 580 nm). The particles are 100 nm in diameter, non-functionalized (plain surface) of dextran-iron oxide composite particles. The particles were kept at 4 °C and are stable in aqueous buffer solutions pH > 4 as the cell culture medium or PBS.

Cells and Culture Conditions

Normal human dermal fibroblasts (NHDFs) and primary human umbilical vein endothelial cells (HUVECs) were purchased from PromoCell (Heidelberg, Germany). NHDFs were cultured in DMEM with 2 mM L-glutamine and 10% FCS. HUVECs were used at passage 2–4 and cultivated in ECGM with supplements at 37 °C and 5.0% CO₂. For further passaging, trypsinisation was performed according to the manufacturer's instructions. The murine macrophage cell line RAW 264.7 was bought from ATCC (Wesel, Germany) expanded as a master cell bank and maintained in RPMI-1640 medium supplemented with 10% fetal bovine serum (FBS) and 100 U mL⁻¹ penicillin (all from Gibco, Germany) and stored at 37 °C with 5% CO₂ in an incubator.

Preparation of Cell-Based Experiments

Cells were seeded into 25 cm² cell culture flasks in a total volume of 5 mL. The amount of seeded cells was calculated to achieve a final confluency of 70% after 24 h. After 24 h, SPION^{PA}M were added to a final concentration of 0.5, 1, 2 and 4 µg_{Fe}/mL cell culture media which corresponds to 0.1, 0.2, 0.4 and 0.8 µg_{Fe}/cm² cell culture plate area. The negative control contained 0 µg_{Fe}/mL cell culture media. For particle uptake, cells were incubated for another 24 h. Subsequently, the samples were washed twice in PBS, harvested, resuspended in 3 mL cell culture media, and transferred into 4 cm tissue culture dishes (maximum size for magnets M2 and M3, see [Supplementary Table S1](#)). Before the magnetic experiments, cell suspensions were used to determine the absolute cell counts and viability with the MUSE[®] Cell Analyzer (Merck-Millipore, Billerica, USA), as well as for SPION quantification measurements using AES spectroscopy (see below). All cell-based experiments were performed in three independent experiments.

For the cell uptake experiments in Raw264.7 cells were seeded at a density of 100000 cells/well in 24-well-plates (Greiner Bio-One, Germany) or at a density of 25000 cells/slide in an iBidi µ-Slides (iBidi, Germany) one day before the incubation with magnetic nanoparticles to attach to the surface of the plate. For the analysis of suspension cells, these were seeded at the same day of the incubation.

Raw264.7 cells incubated with 500 µg/mL of magnetic labelled-nanoparticles for 24 hours in RPMI Medium containing 10% FBS at 37 °C with 5% CO₂ in an incubator. After the incubation, adherent cells were washed with PBS and detached from the culture vessel with 0.25% trypsin (Gibco, Germany), centrifuged at 300 g for 7 minutes and re-suspended in fresh PBS for the analysis. For the adherent cells in the iBidi µ-Slides, those were washed twice with fresh PBS and maintained in PBS for later analysis.

Halbach-Magnet-Based Directed Movement of SPION-Treated Cells

Before placing the magnet setup M2 into the universal mounting frame K-X of a Zeiss Axio Observer.Z1 (Carl Zeiss AG, Oberkochen, Germany), the used objective was equipped with a 30 mm adapter to increase the parfocal length to 45 mm and the light collector under the condenser was removed to give place to magnet M2. Subsequently, the tissue culture dishes containing the cell

suspension were placed into the magnet. Directly before starting the live documentation, the cell suspension was resuspended by pipetting in order to separate already magnetically formed aggregates. The direction of the magnetic force was periodically changed every minute by 90° and the resulting movement of the cells was imaged with 14 frames per second. Analysis of cellular direction and velocity was performed using the video analysis and modelling tool Tracker 5.0.6 from Open Source Physics (<https://physlets.org/tracker/>).

Intracellular localization of the fluorescent, magnetic nanoparticles was imaged using Leica TCS SP5 II on a DMI8 microscope body, which was equipped with an HCX PL APO CS 63x/1.4–0.6 oil-immersion objective. Image processing was done via the Leica LAS AF Software. Alternatively, an Olympus CKX41 microscope equipped with Olympus SC30 camera was used.

Quantification of Cellular SPIONs by MP-AES

The absolute cellular iron content was determined by MP-AES. Two millilitres of the cell suspension used for the Halbach magnet experiments were centrifuged for 5 min at 1000 g. The supernatants were aspirated and the pellets were stored at –20 °C until measurement. The cell pellets were then dissolved in 50 µL nitric acid 65%, incubated at 95 °C for 10 min with a shaking incubator and diluted to 450 µL with ultrapure water. The total iron content of the cells was then determined using the MP-AES method which was described above. The iron content was normalized to the total number of cells analysed with the MUSE® Cell Analyzer.

Results and Discussion

The basic idea in our study is to use permanent magnets for precise displacements of SPIONs by combination of a strong, homogeneous (dipolar) magnetic field (B_0) and a second constantly graded (quadrupolar) field ($dB/dr = G$) superimposed on the first (see Figure 1A–C). The homogeneous field magnetizes and orients all SPIONs evenly, aligns their magnetic moments and thus, transforms themselves into tiny magnets. However, the homogeneous magnetic field does not exert a force on them (see Figure 1E). This force is introduced by the second (quadrupolar) gradient field, which all by itself generates a radial gradient without any directional control other than towards its rim (see Figure 1F). The main point here is that in the

combination of both fields the motion of the particles is driven predominantly by the component of the gradient field, which is parallel to the direction of the homogeneous field. As a result, particles are guided with constant force and in a single direction over the entire inner volume of the magnet system (see Figure 1G). This solves the guiding problem! The physical details of this design are explained elsewhere.²² The most simple realization of this idea is illustrated in Figure 1A–C by a coaxial arrangement of two Halbach cylinders.²³ The direction of the force is simply adjusted by varying the angle between quadrupole and dipole (Figure 1C) and additionally the strength of the force can be scaled by adding another quadrupole. If properly designed this will vary the force between zero and twice that of a single quadrupole via mutual rotation.¹⁸ The experiments presented here were performed in three of such magnet setups (M1 to M3, [Supplementary Figure S1](#); for details see [Supplementary Table S1](#)) with different size and properties because they had to fit into different microscopes. The position of the rotatable quadrupoles was changed manually in all experiments presented in this work.

Recently, we have shown, that SPIONs with hydrodynamic diameters as small as 75 nm can be moved at arbitrary angles with such a magnet setup.²² In this work, we extend this principle on the intracellular manipulation of SPIONs as well as to the movement of entire human cells and cell clusters loaded with SPIONs. Furthermore, we present a novel magnet system with two compensating quadrupoles, which allows for removing the magnetic force enabling stop-and-go movements.

First, the capability of the magnet system in terms of steering is demonstrated. Equipping the magnet system in Figure 1C with a second quadrupole allows not only to move SPIONs in certain directions but also to accelerate them by scaling the magnetic force. Because the quadrupoles are designed such that they both produce essentially the same magnetic flux in the inner volume, an angle of 90° between them extremely reduces the flux/force of the combined gradient to a negligible level. When the quadrupoles are rotated in this compensating configuration to a different angle relative to the dipole and then the angle between is reduced to 0° (i.e., full gradient/force) the particles can be moved even at sharp angles. This gives complete control to manoeuvre magnetic material in the 2D plane of magnet M1 as demonstrated in [Supplementary Video S1](#) by writing the letters JGU with a clearly visible 1 mm steel ball. This magnet was used to induce similar movements including stops of SPION-loaded murine Raw264.7 cells

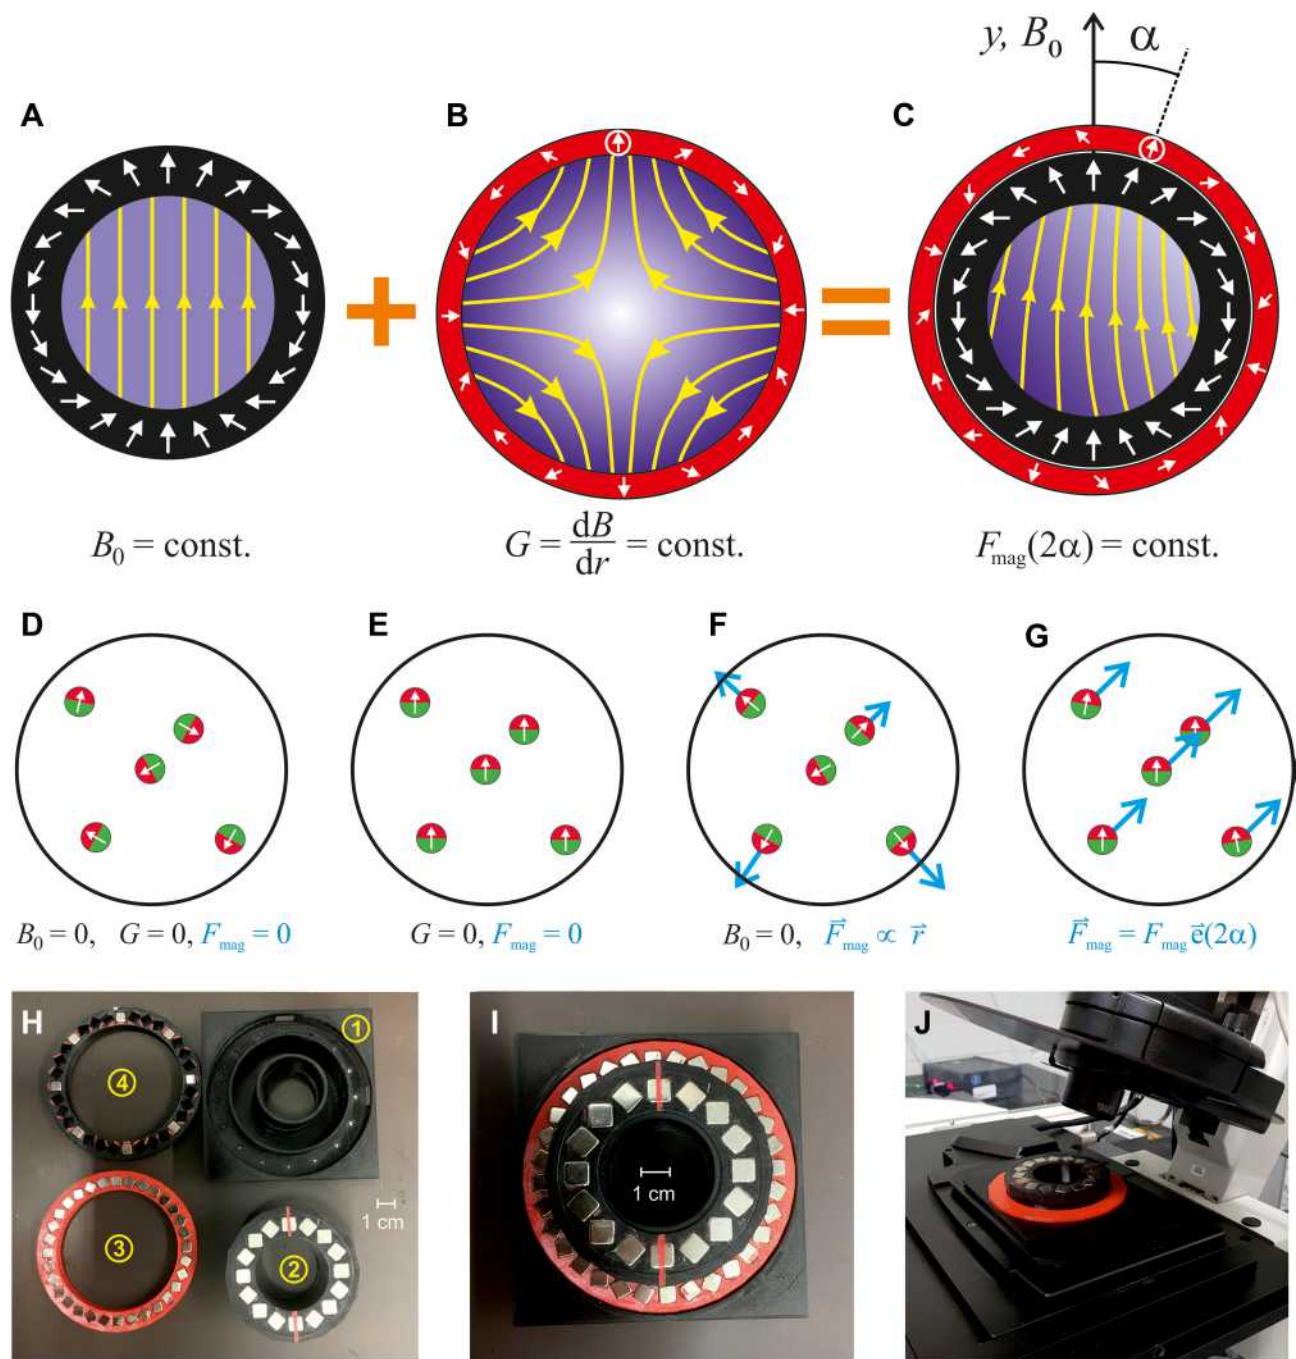

Figure 1 Schematic cross-sections and architecture of a Halbach magnet compatible for microscope systems. **(A)** An ideal Halbach dipole cylinder (black) providing a homogeneous magnetic field, B_0 (magnetic field amplitude is sketched by shades of blue and yellow field lines); **(B)** An ideal Halbach quadrupole (red) generating a constant radial magnetic field gradient. **(C)** In a combined Halbach dipole and quadrupole, only the gradient component along B_0 is relevant to generate the magnetic force (F_{mag}), on particles inside the innermost cylinder (F_{mag} is homogeneous in strength and direction in a distance r from the center if $B_0 \gg Gr$ is fulfilled). The angle of F_{mag} changes by 2α if the quadrupole is rotated by α relative to the dipole. For details see.²² **(D–G)** Effect on some magnetic particles in the inner volume. Here it is assumed that the particles have some remnant magnetization, hence they always possess a magnetic moment. **(D)** In the absence of any magnetic field the particles point in arbitrary directions. **(E)** In a homogeneous field they align with the field, but in the absence of a gradient there is no force on them. **(F)** In the gradient field of a quadrupole, the force (blue arrows) is radial, ie, zero in the centre and increasing with the distance from it. **(G)** the combination of homogeneous and gradient field results in a constant force in one direction. **(H–J)** Magnetic guiding system for microscopes. **(H)** Disassembled system: 1) Support to fit microscope stages using different adaptors. 2) Halbach dipole generating $B_0 = 0.097$ T. Red line indicates poles. 3) Halbach quadrupole completely filled with magnets, producing $G = 1.3$ T/m. 4) Weaker quadrupole with only every fourth magnet present, producing $G = 0.33$ T/m. **(I)** Assembled system with a weight of 273 g. **(J)** System mounted on a Leica TCS SP5 confocal microscope.

(Supplementary Figure S2, Supplementary Video S2). The cells were placed inside the magnet with both quadrupoles in compensating position (Supplementary Figure S2A). In absence of a magnetic force, the cells remained at their initial site without clustering. As soon as the cells were moved by switching on the gradients, longer clusters typically in a needle-shaped arrangement appeared (Supplementary Figure S2B–D) which were caused by the mutual dipolar attraction of the SPIONs in adjacent cells. Since the SPIONs are magnetized in the direction of the dipole, the long axis of such clusters is always parallel to the direction of the homogeneous (dipolar) field, B_0 .

Bright field microscopy of SPION-loaded Raw264.7 cells under the influence of magnet M3 demonstrate the formation of magnetically induced needle-formed aggregates of cells containing intra- and extracellular SPIONs (Figure 2). The tendency to form such aggregates increased with increasing SPION-loading per cell. We did not quantify this effect in detail, but it is easily observable within the Supplementary Videos S3, S4, S5, S6, S7, and S8. Such behaviour might be of great relevance for applications where cells should be linearly aligned to form barriers or scaffolds (eg, to direct the growth of capillary or nerve cells in certain directions²⁴). By comparing Figure 2A (cells before the magnetic fields were applied) with Figure 2D (cells after the application), it can be shown that this aggregation behaviour is reversible.

The magnetic force, F [N], on a single SPION (with magnetic moment m [Am^2]) in such magnet systems with a magnetic flux gradient, G [T/m], is given by an equation ($F = m G = M V G$) demonstrated by Shevkopyas et al,¹² where the magnetic moment is expressed by the more common magnetization, M [A/m], and the particle's volume V .²² However, in a cluster of n SPIONs the force increases up to

n -fold.²⁵ Therefore, the force on a single cell scales more or less with the number of incorporated SPIONs, but in a cell cluster it also depends on the form (eg, a ring or loop vs needle).²⁶ Furthermore, the tendency of cluster formation must depend on the exerted mutual dipolar forces between SPIONs and the cells hosting them. Hence, SPION coating and membrane thickness will play a role. Finally, the observed velocity also depends not only on the magnetic force but also on the hydrodynamic properties of the cluster, adhesive friction, and collision with other clusters. This is the reason why we are hesitant to report forces here, because some of these details are difficult to quantify or not known yet. It is also difficult to estimate the forces from the speed of the cell clusters because an analytical hydrodynamic model for this geometry is not available.

In order to analyse the movements of SPION-loaded human cells more systematically, human umbilical vein endothelial cells (HUVECs) and normal human dermal fibroblasts (NHDFs) were incubated for 24 h with different concentrations of SPIONs. Iron quantification by atomic emission spectroscopy (AES) revealed a linear increase of cell-associated SPIONs with increasing amounts of SPIONs in the cell culture media during incubation (Figure 3). After SPION incubation and subsequent detachment by trypsinization, the SPION-loaded cells were placed inside the magnet system M2 and moved on a square path by changing the direction of the quadrupole by 45° every minute (Figure 4, Supplementary Figures S3–S7 and Supplementary Videos S3, S4, S5, S6, S7, and S8). The resulting movement at twice that angle (see Figure 1C) of the cells was imaged with 14 frames/s. A detailed analysis of the cellular direction and velocity was performed using the video analysis and modelling tool Tracker 5.0.6 (Open Source Physics). While the magnetically induced average velocity of NHDF cells and

Figure 2 Magnetically based directed cell cluster formation. (A–D) Raw264.7 cells were incubated with magnetic nanoparticles at $500 \mu\text{g/mL}$ and analysed after 24 h incubation in an inverted microscope for magnetically based cluster formation. (B and C) In presence of the magnet system M3, SPION-loaded cells aggregate and form long pole-ladder like structures. (D) These structures were largely reversible, although some of them remained present after removing the magnet system.

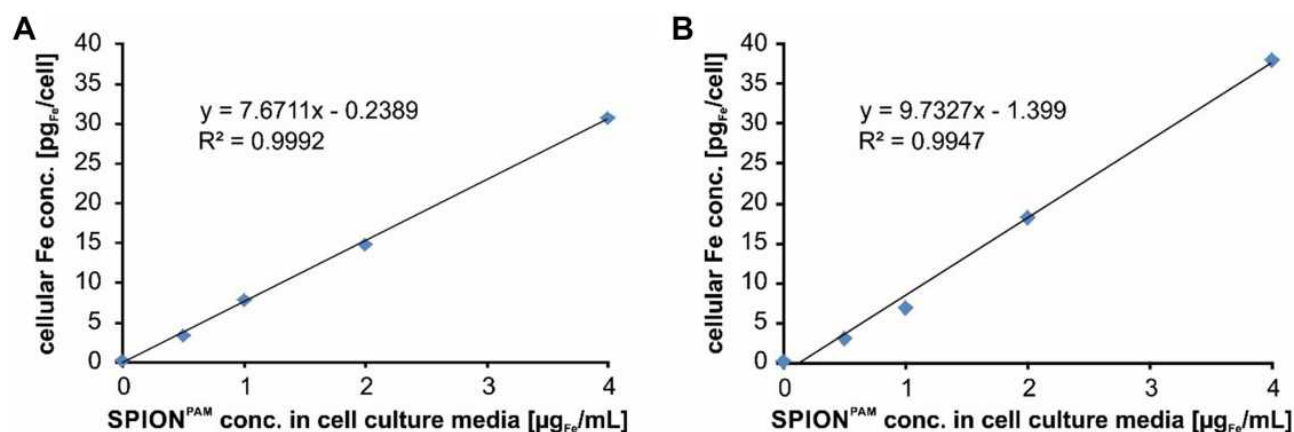

Figure 3 Cellular SPION uptake. To investigate the cellular SPION uptake, HUVECs and NHDF cells were seeded into 25 cm² cell culture flasks. After 24 h, the cells were incubated for another 24 h with 0, 0.5, 1, 2, and 4 µg_{Fe}/mL SPION^{PAM}. To determine the absolute iron concentration of cells, we analysed the cell suspensions to determine the absolute cell counts with the MUSE[®] Cell Analyzer and subsequently quantified the iron amount using AES spectroscopy. **(A)** In HUVECs the iron amount increased from 3.2, 7.7, 14.8, and 30.6 pg_{Fe}/cell and **(B)** in NHDF cells, the iron amount increased from 3.0, 6.8, 18.2, and 37.9 pg_{Fe}/cell revealing a similar amount and linear uptake or cell association of SPIONs in the two cell lines. R2 represents the coefficient of determination. y describes the mathematic relationship between SPION concentration within the cell culture media and cellular iron content.

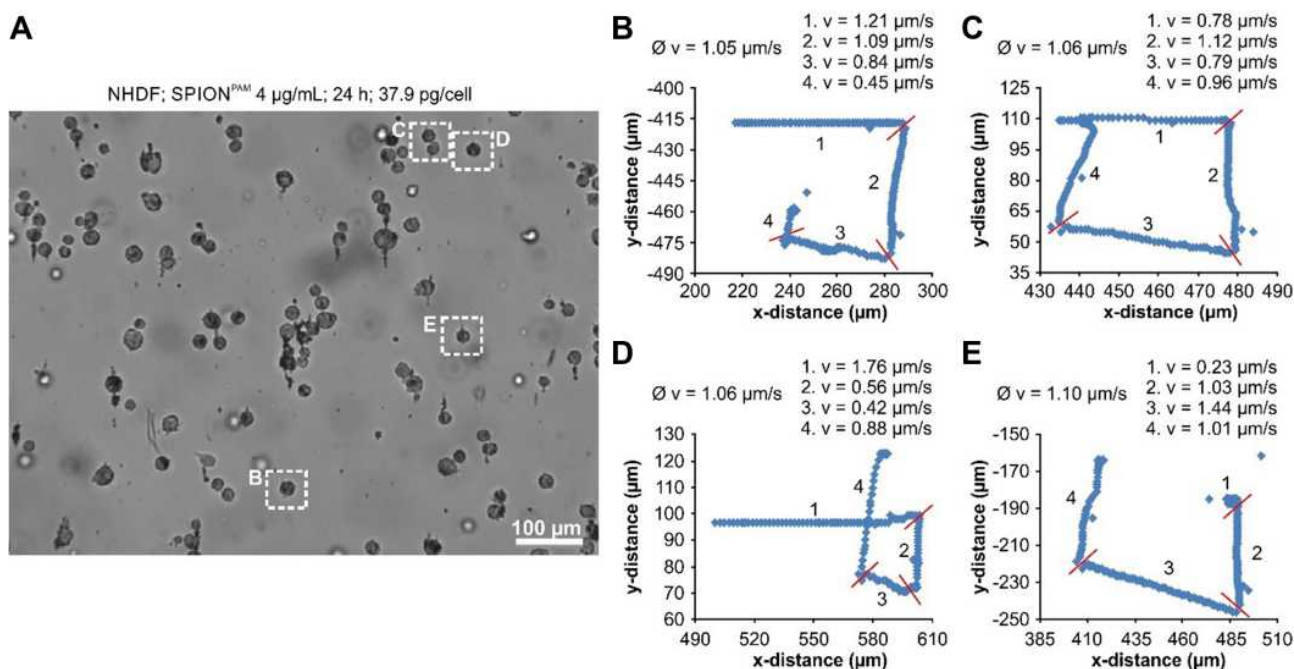

Figure 4 Contact-free movement of SPION-loaded cells. **(A)** Starting frame of the [Supplementary Video S5](#) used for cell tracking of NHDF cells incubated for 24 h with 4 µg/mL SPION^{PAM}. The length of the videos is 4 minutes and after each minute the orientation of the quadrupole magnet was turned by 45°, which changes the direction of the magnetic force by 90°. **(B–E)** Cell tracking of the 4 different cells, marked in [Figure 3A](#) by dashed rectangles. \bar{v} , average velocity; during the first, second, third, and fourth minute (1.v, 2.v, 3.v, 4.v); red bars, changing point of the magnetic force direction. Quantification was performed using the video analysis and modelling tool Tracker 5.0.6 from Open Source Physics.

cell clusters increased only slightly with increasing SPION loading, HUVECs incubated with 4 µg/mL SPIONs exhibited significantly increased velocity compared with NHDFs ([Figure 5](#)). Because cellular SPION loading after incubation with 4 µg/mL SPIONs showed similar values in HUVECs and NHDFs (30.6 pg/cell and 37.9 pg/cell, respectively) ([Figure 3](#)), the average velocity depends not only on the

SPION concentration but also on the cell type. Despite a linear increase of cell-associated SPIONs, the velocity of SPION-containing cells did not increase accordingly, but showed a trend. Most likely, several factors, such as individual cellular SPION-load, adhesive friction, remaining or newly expressed surface proteins for cell attachment and collision with attaching or slow moving cells or cell clusters,

Figure 5 Summary of the magnetically induced velocities of SPION-loaded HUVEC and NHDF cell and cell clusters. HUVECs and NHDFs were incubated for 24 h with 1 µg/mL to 4 µg/mL SPION^{PAM}. After SPION incubation, SPION-loaded cells were detached from the surface by trypsinization, placed inside the magnet system M2 and moved on a square path by changing the direction of the quadrupole by 45° every minute. Velocities were determined from [Supplementary Videos S3, S4, S5, S6, S7, and S8](#). Data are expressed as standard deviation of the velocity of 16 cell and cell clusters. Statistical significances between SPION-loaded HUVEC and NHDF cells are indicated with * and **. The respective confidential intervals are $p \leq 0.05$ and $p \leq 0.0005$, respectively, and were calculated via Student's t-test.

rearrangement of the SPIONs inside the cells after changing the field direction, together with inhomogeneities of the magnetic field complicate the situation and demand a more detailed study.

So far, the magnetic effects of cell-associated SPIONs were only studied by magnetically based movements of non-attached cells or clusters. To investigate the movement of intracellular SPION, we used RAW264.7 cells, a mouse macrophage-like cell line, loaded with fluorescence-labelled SPIONs. After adherence of the cells to the surface, the magnetic force of magnet M3 was not capable to induce a cellular movement. However, the SPIONs were clearly oriented in the direction of the magnetic force (see [Supplementary Figure S8](#)). Moreover, to investigate whether

the SPIONs could be directed by solely changing the orientation of the homogeneous field B_0 , the quadrupole of the magnet M3 was removed, so that a strong magnetic force was no longer present. Without the quadrupole, the SPIONs still formed chains, which were aligned by the homogeneous field of the dipole ([Figure 6](#)). Interestingly, the SPIONs inside the cells strictly followed the rotation of the dipole, so that they were moved through the cytoplasm. This stirring effect can of course be combined with the steering option of the system. By this, intracellular compartments, such as SPIONs-loaded endosomes, can be moved inside a cell. Potentially this gives the opportunity to give the intracellular compartments a directional distribution. We foresee that this could be interesting for producing or inducing polarized cell types. Polarized cell types are typically lining two compartments like the gastrointestinal tract. Here one side is being exposed to the enzymatically digested food (luminal side) and the other facing the blood (basal or basolateral side). Therefore, transporters of food ingredients need to be differentially present on the luminal and basolateral side.

Conclusion

In [Supplementary Video S1](#), we demonstrated complete 2D control by writing the initials of the University of Mainz with a small (still visible) steel ball in a very viscous silicone oil. Moreover, this magnetic system offers complete steering control for SPIONs or SPION-loaded cells or cell clusters. The great advantage of using only permanent magnets for the device is the complete lack of electrical power for the generation and control of the magnetic fields. Of course a computer controlled version of this system will use servos to move the magnetic rings, but the power for this will still be small compared to the power needed to generate magnetic fields of similar strength.²⁷ Furthermore, it is much easier to scale

Figure 6 Magnetically based intracellular SPION reorganization. (A–D) Raw264.7 cells were incubated with fluorescent magnetic nanoparticles at 500 µg/mL and analysed after 24 h incubation by confocal laser scanning microscopy (CLSM) under a magnetic field at 0°, 45° and 0°, respectively (white encircled arrow). For this experiment, the quadrupole of magnet system M3 was removed and only the dipole was rotated.

permanent magnet systems, because using larger magnets essentially means adding more material while larger electro-magnets have to cope with larger inductance, power, and heat management. The use of permanent magnets for controlled movement of magnetic particles was countered mainly by the argument that the magnetic attraction is always towards the poles and that the magnetic field cannot be switched off. We have proved the opposite with the instrumentation introduced in.²² We are not the first who have managed to steer magnetic particles with permanent magnets (see review²⁸) but our magnet system has the great advantage that the magnetic force is constant over the inner volume which simplifies use and scaling its size (an estimation for a whole body system is given in²²). There are no moving robotic arms or moving magnets with substantial forces between them. The rotation of the magnetic rings in our device is almost force free. The use of a homogeneous alignment field also causes clustering of the particles which strongly increases the force. Principally the system is not limited to 2D but 3D operation was not demonstrated yet.

The fact that 2D-steering not only works with SPIONs but also with cells, which are associated to or have incorporated SPIONs, opens up new applications. Cells can be guided to specific locations in the body to introduce a directed and structured growth of tissue or to affect diseased tissues or tumors. So far, we have only demonstrated the magnetic systems using in vitro experiments. However, in vivo applications are potentially possible but might be hampered by higher viscosities, strong blood flow (eg, in larger vessels), and complicated paths and boundaries. Especially, the visualization of the guiding procedure is highly challenging. However, magnetically based imaging of SPIONs is possible since those particles, especially super paramagnetic iron oxide nanoparticles used in our experiments, have been extensively investigated as contrast agents for magnetic resonance imaging (MRI).^{29,30} Similarities between MRI, which need a strong homogeneous field and variable magnetic field gradient indicate the principal possibility that such magnet setups cannot only steer SPIONs but also image them.^{18,31,32} Additionally, such magnet systems can also be used to move other super para- or ferromagnetic objects used in micro-fluidics, nano- and micro-robotics³³ or nanoscience.³⁴

Nanotechnology, Science and Applications

Publish your work in this journal

Nanotechnology, Science and Applications is an international, peer-reviewed, open access journal that focuses on the science of nanotechnology in a wide range of industrial and academic applications. It is characterized by the rapid reporting across all sectors, including engineering, optics, bio-medicine, cosmetics, textiles, resource sustainability and science. Applied research into nano-materials, particles,

nano-structures and fabrication, diagnostics and analytics, drug delivery and toxicology constitute the primary direction of the journal. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
