Background: The risk of hypoxemia increases with the progression of chronic obstructive pulmonary disease (COPD) and the deterioration of pulmonary function. The aim of this study was to compare functional capacity, physical activity, and quality of life in hypoxemic and non-hypoxemic patients with COPD.

Methods: Thirty-nine COPD patients (mean age: 62.0±7.03 years) were included in this study. Arterial blood gas tensions were measured, and patients were divided into two groups according to oxygen partial pressure (PaO₂), the hypoxemic COPD (PaO₂ <60 mmHg) (n=18), and the control (PaO₂ ≥60 mmHg) (n=21) groups. Functional exercise capacity was evaluated using the 6-minute walk test (6MWT). Oxygen saturation, dyspnea, and fatigue perception were measured before and after the 6MWT. Physical activity was assessed using the International Physical Activity Questionnaire (IPAQ) and an accelerometer. Quality of life was assessed using the St George's Respiratory Questionnaire (SGRQ).

Results: The number of emergency visits and hospitalizations were higher in hypoxemic patients ($P<0.05$). Lung function parameters, 6MWT distance, exercise oxygen saturation, IPAQ total score, and energy expenditure during daily life were significantly lower, but percentage of maximum heart rate reached during the 6MWT was significantly higher, in hypoxemic COPD patients than in controls ($P<0.05$).

Conclusion: Hypoxemia has a profound effect on functional capacity and physical activity in patients with COPD.

Keywords: COPD, hypoxemia, 6-minute walk test

Introduction

Chronic obstructive pulmonary disease (COPD) is one of the leading diseases causing mortality and morbidity.¹ The progression of disease and deterioration in pulmonary function increases alveolar hypoxia and ultimately the risk of hypoxemia.² The greatest contributing factor to hypoxemia is ventilation/perfusion mismatch resulting from progressive airway limitation and emphysematous destruction of the pulmonary capillary bed. Dynamic hyperinflation, total lung capacity, cardiovascular factors such as oxygen consumption and cardiac output, nutritional status, and female sex also contribute to the risk of hypoxemia.³⁻⁶

Hypoxemia and tissue hypoxia cause systemic imbalance and inflammation. Protein synthesis is reduced and muscle cell structure is altered in hypoxemia. Complications and extrapulmonary comorbidities including cardiovascular disorders, pulmonary hypertension, polycythemia, neurocognitive dysfunction, impairment of life quality, lower exercise tolerance, and skeletal muscle weakness are common, and the risk of death is increased with the presence of hypoxemia in COPD.⁷⁻⁹

Hypoxemia leads to the conversion of aerobic metabolism to anaerobic metabolism in low levels of physical activity in COPD.¹⁰ Physical inactivity is considered an important marker of advanced COPD. Reduced skeletal muscle oxidative capacity can have a negative effect on exercise capacity and physical activity in COPD patients.¹¹

Few studies have examined hypoxemia and related factors including exercise capacity, muscle function, and quality of life.^{6,12,13} To our knowledge, no published study has examined whether quality of life, functional capacity, and physical activity change between hypoxemic and non-hypoxemic COPD patients. Identifying these factors can guide clinicians in the follow-up of COPD patients. The aim of this study was to compare functional capacity, physical activity, and quality of life in hypoxemic and non-hypoxemic patients with COPD.

Methods

This cross-sectional, observational study included 39 clinically stable COPD (34 male and five female) patients between the ages of 41 and 78 years with a mean forced expiratory volume in 1 second (FEV_1) of $50.64\% \pm 23.17\%$. Diagnosis of disease and classification of disease severity were established in line with the Global initiative for chronic Obstructive Lung Disease (GOLD) criteria. Patients who were not able to walk or perform the 6-minute walk test (6MWT), patients who were not able to cooperate in pulmonary function testing, patients with oral corticosteroid use for at least 6 weeks, and patients with heart disease and acute exacerbation were not included in the study. According to arterial blood gas analysis, patients with oxygen partial pressure (PaO_2) of <60 mmHg were assigned to the hypoxemic COPD group and patients with $PaO_2 \geq 60$ mmHg were assigned to the non-hypoxemic control group. The hypoxemic group consisted of 18 patients and the non-hypoxemic control group consisted of 21 patients. The study was approved by the Ethics Committee of Hacettepe University, Ankara, Turkey, and signed informed consent forms were obtained from each patient before the study.

Physical, physiological, and sociodemographic data of the patients were recorded. Body mass index was calculated by the following formula: $\text{body weight}/\text{height}^2$ (kg/m^2).¹⁴ The patients' smoking history was recorded as pack-years.

The lung function test was performed in a seated position using a Spirolab III spirometer (Medical International Research, Rome, Italy) consistent with American Thoracic Society (ATS)/European Respiratory Society (ERS) guidelines. Forced vital capacity (FVC), FEV_1 , FEV_1/FVC rate, peak expiratory flow, and forced expiratory flow between 25% and 75% of FVC ($FEF_{25\%-75\%}$) were recorded. Lung function

test parameters were expressed as percentage of the predicted values for age, height, body weight, and sex.^{15,16}

Resting arterial blood gas analysis was performed in environmental air, with radial arterial blood collected to analyze the concentration of hydrogen ions (pH), PaO_2 , partial carbon dioxide pressure, and oxygen saturation. We used the AVL Compact I (AVL Medical Instruments A.G., Schaffhausen, Switzerland) blood gas analyzer to adjust these variables. The alveolar-arterial oxygen gradient ($P[A-a]O_2$) was calculated using the measured PaO_2 and partial carbon dioxide pressure assuming a standard respiratory exchange ratio of 0.8.

The 6MWT was performed according to ATS guidelines.¹⁷ Patients were asked to walk quickly along a 30 m level corridor for 6 minutes, and the total distance walked was recorded as meters. The test was carried out twice with a 30-minute interval. The best value of the two tests was used for statistical analysis. Heart rate and oxygen saturation were recorded during the 6MWT using a pulse oximeter (KPTS-01, Seoul, South Korea). Fatigue and dyspnea perception were assessed using the modified Borg rating of perceived exertion scale scores before and after the test.¹⁸

Physical activity was determined using the self-administered short form of the International Physical Activity Questionnaire (IPAQ).¹⁹ The IPAQ requires respondents to estimate time spent in various levels of physical activity during the previous week. Scores for walking and moderate and vigorous activities are calculated as durations and frequencies multiplied by known metabolic equivalents per activity. The results for all activity-based items are summed for the total physical activity score. An item regarding time spent sitting is not included in the total physical activity score and is a separate score expressed as minutes.²⁰

Daily energy expenditure was measured for 4 consecutive days (2 weekdays and 2 weekend days) using the Caltrac accelerometer (Muscle Dynamics Fitness Network, Torrance, CA, USA). Patients were asked to continue their typical daily physical activities. For data analysis, the average energy expenditure during the 4 days was used.

The St George's Respiratory Questionnaire (SGRQ) was used to assess quality of life. The SGRQ has 76 items that are divided into three sections including symptoms, activity, and impacts. Scores for each section and the total score range from 0–100, with high scores indicating poor health status.²¹

Statistical analysis

Statistical analysis was performed using the Statistical Package for the Social Sciences (SPSS) version 18.0 software

(SPSS Inc., Chicago, IL, USA). We used the Shapiro–Wilk test to test the normal distribution of the arterial blood gas analysis, spirometry, the 6MWT, physical activity, and the SGRQ. Comparison between hypoxemic and non-hypoxemic COPD was performed using the Mann–Whitney *U* test. Chi-Square test was used for IPAQ categorical classification. Kruskal–Wallis rank sum test with post hoc analysis was used to compare normal and higher gradient levels of the hypoxemic group to the non-hypoxemic group. The level of statistical significance was set at $P<0.05$ for all analyses.²²

Results

Thirty-nine patients entered the study (21 non-hypoxemic, 18 hypoxemic), and none of them were excluded during the measurements. Five patients in the hypoxemic COPD group were prescribed supplementary oxygen therapy. Patients' characteristics are shown in Table 1. There were no significant differences in age, sex, height, weight, body mass index, disease duration, and smoking history between the two groups ($P>0.05$).

According to GOLD phenotypes, seven (33%) patients were in group A, ten (47.6%) patients were in group B, three (14.3%) patients were in group C, and one (4.8%) patient

was in group D classification level among the non-hypoxemic patients. In the hypoxemic patient group, one (5.6%) patient was in group A, five (27.8%) patients were in group B, and 12 (66.7%) patients were in group D classification level. There was a significant difference between the groups when classified by GOLD ABCD index, and patients in the hypoxemic group were more likely to be in higher-risk GOLD classes ($P<0.05$). Higher GOLD severity classification was significantly correlated with hypoxemia ($r=-0.645$, $P<0.001$). GOLD ABCD classification was correlated with 6MWT distance ($r=-0.625$, $P<0.001$), IPAQ total score ($r=-0.355$, $P=0.03$), IPAQ walking score ($r=-0.373$, $P=0.02$), daily energy expenditure ($r=-0.468$, $P=0.003$), SGRQ total score ($r=0.565$, $P<0.001$), SGRQ symptom subdomain ($r=0.560$, $P<0.001$), SGRQ activity subdomain ($r=0.495$, $P=0.002$), and SGRQ impact subdomain ($r=0.527$, $P=0.001$).

The numbers of emergency visits and hospitalizations were higher in the hypoxemic patients ($P<0.05$). Lung function test findings were significantly lower in the hypoxemic patients ($P<0.05$) (Table 1).

Functional capacity, physical activity, and quality of life variables are shown in Table 2. The 6MWT distance and exercise oxygen saturation were significantly lower and

SGRQ total score (0–100)	53.96±22.55	44.73±19.64	0.158

Notes: Values are expressed as mean ± standard deviation. * $P < 0.05$.

Abbreviations: COPD, chronic obstructive pulmonary disease; 6MWT, 6-minute walk test; %HRmax, percentage of maximal heart rate; SpO₂, oxygen saturation with pulse oximeter; MET, metabolic equivalent; IPAQ, International Physical Activity Questionnaire; SGRQ, St George's Respiratory Questionnaire.

percentage of maximum heart rate reached during the test was significantly higher in hypoxemic COPD patients compared to the non-hypoxemic group ($P < 0.05$) (Table 2).

The IPAQ total score and energy expenditure during daily life were significantly lower in hypoxemic patients ($P < 0.05$) (Table 2). Six (35%) patients were inactive, ten (59%) patients were minimally active, and one patient (6%) was sufficiently active in the hypoxemic group, whereas two (9%) patients were inactive, 14 (67%) patients were minimally active, and five patients (24%) were sufficiently active among the non-hypoxemic patients according to IPAQ categorical classification ($P < 0.05$). No significant difference in time spent sedentarily, measured using the sitting time score of IPAQ, was observed between the two groups ($P > 0.05$) (Table 2).

There were no significant differences in SGRQ total and subscale scores between the hypoxemic and the non-hypoxemic patients with COPD ($P > 0.05$) (Table 2).

According to P(A-a)O₂ gradient, eleven (61.1%) patients had a higher gradient level assuming low ventilation/perfusion ratio and seven (38.9%) patients had a normal P(A-a)O₂ level due to hypoventilation in the hypoxemic COPD group. All patients had a normal gradient in the non-hypoxemic group. Post hoc analysis revealed no differences when the normal and higher gradient hypoxemic groups were compared to the non-hypoxemic group ($P > 0.05$).

Discussion

The current study has two main findings: 1) more frequent emergency visits and hospitalization and 2) reduced lung

function, functional exercise capacity, and physical activity level in daily life in hypoxemic patients with COPD. Higher GOLD severity classification was significantly correlated with hypoxemia in patients with COPD.

Emergency department visits and hospitalizations are an important risk of disease progression and are the predictors of acute exacerbations in COPD. They are related with morbidity, mortality, worsened health status, and impaired lung function.^{23,24} In this study, we showed that the presence of hypoxemia may have an effect on number of emergency visits and hospitalizations. Implementation of a comprehensive self-management strategy, especially including oxygen therapy, may result in a lower hospitalization rate and fewer emergency department visits. COPD patients who experienced exacerbations and a higher hospitalization rate have shown markedly lower skeletal muscle strength, 6-minute walk distance, physical activity, and quality of life.²⁵

The decline of PaO₂ was in line with a decrease in FEV₁, FVC, peak expiratory flow, and FEF_{25%–75%} in COPD patients in our study. Airway obstruction reduces ventilation and causes ventilation/perfusion mismatch. One study showed that airflow limitation increased progressively with arterial blood gas disturbances.²⁶ A multicenter 3-year follow up study also demonstrated that lower levels of PaO₂ were associated with a higher functional residual capacity and total lung capacity that reflects the degree of hyperinflation.²⁷

Functional exercise capacity measured using the 6MWT was markedly reduced in our hypoxemic patients. Romer et al showed that the reduction in PaO₂ negatively impacted

functional capacity and fatigability in healthy individuals with skeletal muscle dysfunction.²⁸ Exercise performance depends on aerobic metabolism and oxidative capacity. Hypoxemia has been linked to a more glycolytic muscle profile and ultimately with the decline in 6MWT.¹² Our hypoxemic patients also experienced more severe oxygen desaturation during the 6MWT. Oxygen desaturation during the 6MWT occurs due to the imbalance between oxygen supply and demand during exercise associated with skeletal muscle dysfunction and hemodynamic and respiratory problems in COPD patients.²⁹ Arterial hypoxemia is associated with poor oxygen transport to the muscles, increasing oxygen desaturation during exercise. This desaturation during exercise increases the risk of poor prognosis.³⁰

We found that patients with hypoxemic COPD were less physically active during their daily life measured using both subjective and objective methods. To our knowledge, this was the first study that reported the physical activity level in hypoxemic patients with COPD. Like exercise performance, physical activity also predominantly depends on the aerobic capacity.³¹ It appears that hypoxemia has a significant impact on physical activity in COPD. Endurance training is known to promote more aerobic muscle performance in COPD, with increases in number of type 1 muscle fibers, mitochondrial density, oxidative enzyme activity, and capillarization.³² Exercise may facilitate gas exchange in patients with COPD by improving the ventilation/perfusion ratio. Supplemental use of noninvasive ventilation, oxygen therapy, and heliox during exercise to enhance the physiological benefits of exercise is not well established and is not routine in clinical practice.³³

Hypoxemia and acidosis affect sympathetic activation and chemoreflex control of heart rate responses.³⁴ Studies showed a relationship between higher resting heart rate and low levels of PaO₂. The presence of hypoxemia increased resting heart rate 49% per ten beats per minute.^{35,36} In accordance with the literature, the hypoxemic patients in our study also exhibited elevated heart rate responses during exercise testing.

Most related studies have demonstrated a significant impairment of quality of life in hypoxemic COPD patients compared to a control group.^{13,37} As was the case in our study, however, a few studies showed no relationship between PaO₂ and quality of life scores.^{38,39} A possible explanation for these findings is that few patients used supplementary oxygen in our hypoxemic group; therefore, there was no improvement in health status resulting from long-term oxygen therapy.

We did not find any differences between hypoxemic patients with normal and higher P(A-a)O₂ gradient levels compared to the non-hypoxemic group. However, there were

very few patients in each group. Further research with larger patient numbers is needed to investigate the effect different causes of hypoxemia have on functional parameters.

Our study had limitations which must be taken into consideration. The small sample size may not allow for the determination of the relationship between hypoxemia and quality of life in COPD. Measurement of static lung volume and diffusing capacity of the lungs for carbon monoxide can yield more information about the relationship between hypoxemia and lung function. However, we showed for the first time in the literature that functional capacity, physical activity, and exercise heart rate change between hypoxemic and non-hypoxemic COPD patients.

Conclusion

We can conclude that hypoxemia is an important variable to detect reductions in lung function, functional exercise capacity, and physical activity level in patients with COPD. Arterial hypoxemia and lung function deterioration have a main negative impact of limitation of exercise capacity in COPD. Further study is needed to investigate the effects of long-term oxygen therapy on functional capacity and physical activity in patients with hypoxemic COPD.

International Journal of COPD

Publish your work in this journal

The International Journal of COPD is an international, peer-reviewed journal of therapeutics and pharmacology focusing on concise rapid reporting of clinical studies and reviews in COPD. Special focus is given to the pathophysiological processes underlying the disease, intervention programs, patient focused education, and self management protocols.
