Abstract: The tumor cell (TC) PD-L1 expression has been reported by several studies in various types of cancer, and it reduces the cytotoxicity of T-cells toward cancer and evades the anticancer immune response. Herein, our study focuses on the impact of PD-L1 expression in prognosis and the correlation with clinical prognostic factors for local advanced rectal cancer with neoadjuvant radiotherapy (RT). A total of 68 rectal cancer patients treated with neoadjuvant RT were retrospectively enrolled in the present study. PD-L1 expression was investigated using immunohistochemistry. A regression model was used to identify prognostic factors associated with the disease-free survival, the local recurrence-free survival (LRFS), and the overall survival rates. The median follow-up was 32.5 months. Seven patients presented TC PD-L1 positive (TC PD-L1+), while the others were TC PD-L1 negative (TC PD-L1-). TC PD-L1+ patients showed frequent tumor recurrence than TC PD-L1- patients. Several patients with TC PD-L1- underwent long-course RT. TC PD-L1 expression was similar to interstitial cell (IC) PD-L1 expression, and the relationship between IC PD-L1 and pathological T stage was observed. TC PD-L1+ was related to poor LRFS. The multivariate analysis showed TC PD-L1+ as an independent negative prognostic factor for LRFS. In conclusion, TC PD-L1 expression putatively predicts the LRFS for patients with rectal cancer following neoadjuvant RT. The patients with TC PD-L1+ are susceptible to high local recurrent rate, thereby proposing a novel immunotherapeutic strategy for PD-L1 inhibition-mediated control.

Keywords: PD-L1, rectal cancer, neoadjuvant radiotherapy, prognosis

Introduction

Rectal cancer is the third most common form of cancer worldwide, with an estimated 134,490 new cases diagnosed in 2016 in the USA and ~49,190 cases succumbing to mortality.¹ For the local advanced rectal cancer (LARC) patients, current treatment strategies include preoperative radiotherapy (RT) or chemoradiotherapy, surgery, and chemotherapy.² In addition, immunotherapy has been regarded as a promising therapeutic approach in anticancer treatment and has been investigated for several years. Although some studies had shown that rectal cancer patients are sensitive to immunotherapy, only small benefits in clinical practices have been achieved.³ The current success achieved through the inhibition of immune checkpoint pathways, such as programmed death 1 (PD-1) pathway, is a breakthrough in immunotherapy.

PD-1 is an inhibitory molecule that suppresses the proliferation of T-cells and the effector functions of activated T-cells through interaction with its ligand, the programmed death-ligand 1 (PD-L1).⁴ PD-L1 exhibits a broad tissue distribution and can provide inhibitory signals to PD-1+ immune cells for suppressing the immune

responses.⁵ A majority of the tumor cells (TCs) can upregulate the expression of PD-L1, and thus, this mechanism may be advantageous to reduce the cytotoxicity of T-cells toward cancer and evade the anticancer immune response.^{6,7}

Importantly, previous studies have shown that the TC PD-L1 expression is related to the response of anti-PD-1/PD-L1 therapies.⁸ In clinical application, the blockade of PD-1 has led to antitumor activity and is certified by the US Food and Drug Administration (FDA) to treat melanoma and non-small-cell lung cancer patients.⁹ Interestingly, RT was shown to upregulate TC PD-L1 expression through modulating the radiation-induced biological effects.¹⁰ In addition, a series of preclinical studies has shown that the synergism of anti-PD-L1/PD-1 therapy and radiation could achieve better outcomes as compared to radiation alone in mice.^{11,12}

In the case of rectal cancer, the study regarding the effect of PD-L1 expression (negative vs. positive) in patients with neoadjuvant RT is yet limited. Hence, the purpose of the present study was to investigate the impact of PD-L1 expression on the outcomes of patients with rectal cancer following neoadjuvant RT.

Patients and methods

Patients

We retrospectively examined formalin-fixed and paraffin-embedded tumor tissue specimens of 80 patients who underwent preoperative RT at Fujian Provincial Cancer Hospital, Fuzhou, China, from June 2006 to February 2015. We conducted the research after the ethical approval of our institution. Of these, five patients were excluded from participation due to an exhibition of complete pathological response. Specimens from five cases were in poor condition, and two were not available. Finally, 68 patients were analyzed in this study. All tumor samples were diagnosed as rectal adenocarcinoma by pathologists. Patients who did not display distant metastasis at diagnosis and patients with more than one malignancy were excluded from the analysis. The study was approved by the ethics committee of Fujian Cancer Hospital, Fuzhou, China (No. YKT2016-025-01). As a retrospective study which involved review of patient medical records and tumor specimens, individual consent was not required by our ethics committee which approved the study as no individual patient identifiable information was utilized.

Treatment

The RT regimen consisted of short-course radiotherapy (SCRT) and long-course radiotherapy (LCRT), which was delivered using a conventional two-dimensional technique or intensity-modulated radiation therapy (IMRT). The SCRT

was delivered in a dosage of 25 Gy in five fractions, while the LCRT consisted of a dose of 50.4 Gy in 28 fractions with a boost to the 2 cm margin of gross disease after delivering 45 Gy. In the two-dimensional conventional RT, the whole-pelvic radiation-treated field encompassed the primary tumor and the nodes at risk, which was the region prior to the periphery of the sacrum and inferior to symphysis pubis, respectively. The clinical target volume in IMRT included the primary tumor and anorectal, mesorectal, pre-sacral, and internal iliac lymph nodes. 5-Fluorouracil (5-FU)-based chemotherapy was performed routinely. All patients received total mesorectal excision (TME), including low anterior resection (LAR) and abdominoperineal resection (APR). Surgery was conducted 1 week after the SCRT and 6–8 weeks after the LCRT was delivered.

Immunohistochemistry (IHC)

IHC was performed on 4- μ m-thick tumor specimen sections in paraffin-embedded blocks. The slides were deparaffinized using xylene and rehydrated using an alcohol gradient. Subsequently, the sections were washed in PBS/0.05% Tween followed by endogenous peroxidase ablation using 3% peroxide-methanol to block the paraffin sections at room temperature. Followed by cooling at room temperature for 20 min, the tissue sections were boiled in EDTA buffer, pH 8.0, for 10 min for antigen retrieval. The nonspecific binding of antibodies would then be blocked. The slides were probed with rabbit anti-human PD-L1/CD274 monoclonal antibody (Clone SP142) (M4420, 0.1 mL, 1:100; Spring Bioscience, Pleasanton, CA, USA) at 4°C overnight or 37°C for 1 h. The primary antibody was incubated on the slides for 10 min at room temperature. After rinsing the slides twice for 5 min per wash with PBS/0.05% Tween, 3,3'-diaminobenzidine was used for staining at room temperature without light for 10 min followed by counterstaining with hematoxylin. Two experienced investigators including one general pathologist, who were blinded to any clinical information, independently evaluated the expression of PD-L1. All reactions were conducted using positive and negative controls.

Follow-up

The patients' data were retrospectively analyzed. All patients were assessed clinically every 3 months for 2 years, every 6 months for 5 years, and annually after that. The tumor progression was diagnosed as local recurrence and distant metastasis either pathologically or radiologically. The local recurrence was defined as relapse in regions adjacent to the tumor bed or at the area of the anastomosis.

Statistical analysis

The end point of this analysis included disease-free survival (DFS), local recurrence-free survival (LRFS), and overall survival (OS) rates. The time to event was estimated from the date of rectal surgery to the date of the event. The event for the DFS was defined as disease progression, relapse, or death; the LRFS was considered as relapse or death, and the OS was defined as death from any cause. The clinicopathological factors were compared between the groups using χ^2 or the Fisher's exact test. The Kaplan–Meier method and log-rank tests were conducted for survival curve analysis and statistical differences. The prognostic relevance of variables was examined by the Cox regression model. *P*-value < 0.05 in all the statistical tests was regarded as significant. The statistical analyses were conducted using the SPSS version 22.0 (IBM Corporation, Armonk, NY, USA).

Results

Patient characteristics

A total of 68 patients who were treated with neoadjuvant RT were eligible for analysis in this study. The patient's characteristics are summarized in Table 1. The median follow-up time was 32.5 months (range, 2–152 months). The cohort comprised of 46 (67.6%) males and 22 (32.4%) female patients. The median age of the patients analyzed was 53.5 years (range, 22–87 years). Patients with clinical TNM stages II and III were 27 (39.7%) and 41 (60.3%), respectively. Of all the patients, those with clinical T-stages 2 and 3 (cT2/3) were 36 (52.9%), and the rest had a cT4 stage. Those with the pathological T stage after neoadjuvant treatment (ypT) 2, 3, and 4 were 13 (19.1%), 39 (57.4%), and 16 (23.5%), respectively. In all, 42 (61.8%) patients presented clinical lymph node-positive disease (cN1/2), while the pathological N stage (pN) was pN1 in 24 (35.3%) and pN2 in 15 (22.11%) patients. In all, 17 (25%) patients were identified as low grade and 51 (75%) as an intermediate grade. With respect to the tumor location, 47 (69.1%) patients had low rectal cancer (0–5 cm distant to verge), while 21 (30.9%) patients had >5–10 cm distance to verge. A total of 16 (23.5%) patients had carcinoma nodules, 16 (23.5%) patients had venous invasion, and 13 (19.1%) patients had neural invasion. In all, 40 (58.8%) patients received SCRT and the rest received LCRT. A total of 28 (41.2%) patients received LAR and 20 (29.4%) patients underwent preoperative chemotherapy (pre-CT).

Expression of PD-L1 in rectal cancer

IHC staining detected PD-L1 localization both in the TCs and non-cancerous interstitial cells (ICs; Figure 1). PD-L1

expression was shown in both the cytosol and cell membranes in rectal cancer samples. The level of PD-L1 expression was quantified on the basis of percentage of the stained area. PD-L1 expression in TCs was low for most patients, while that in ICs was relatively high (Figure 2). We defined TCs with <1% of positive cells and ≥1% of positive cells as PD-L1 negative (PD-L1-; n = 61, 89.7%) and positive (PD-L1+; n = 7, 10.3%), respectively. With regard to PD-L1 expression in ICs, a cutoff of 10% was used to define “negative” (n = 51, 75%) vs. “positive” (n = 17, 25%) expression.

As shown in Table 2, we compared the outcomes and various clinicopathological factors between the groups. TC

PD-L1+ was significantly correlated to SCRT ($P = 0.036$), and recurrence ($P = 0.044$). No significant differences were observed except for pathological depth of invasion (pT; $P = 0.039$) in ICs. Additionally, PD-L1 protein expression in TCs was correlated to that in ICs ($P = 0.009$).

Impact of PD-L1 on the survival

In order to assess the effect of PD-L1 expression in the TCs and ICs on patients' prognosis, we defined PD-L1 expression as positive expression and negative expression

groups according to the immunostaining signal intensity. Herein, univariate analysis showed that factors affecting DFS were age, pN stage, carcinoma nodules, and TME method ($P = 0.028, 0.023, 0.013,$ and 0.046 , respectively); pN stage, carcinoma nodules, and TC PD-L1+ expression were negative prognostic factors for LRFS ($P = 0.054, 0.022,$ and 0.010 , respectively). The factors affecting OS were a venous invasion and pathological differentiation ($P = 0.055$ and 0.020 , respectively). The multivariate Cox regression model showed that the TC PD-L1+ expression (hazard ratio [HR] 6.001, 95% CI = 1.383–26.014, $P = 0.017$) was associated with LRFS. Furthermore, the pathological differentiation (HR 0.310, 95% CI = 0.116–0.831, $P = 0.020$) was the independent prognostic factor (Tables 3–5). LRFS according to PD-L1 expression in TCs is shown by Kaplan–Meier curves in Figure 3. Patients with TC PD-L1+ had a significantly unfavorable prognosis in contrast to patients with TC PD-L1–.

Discussion

The present study focuses on the impact of PD-L1 expression in prognosis and the correlation with clinical prognostic factors for LARC with neoadjuvant RT. Here, we found that TC PD-L1+ was associated with tumor recurrence, and a correlation between IC PD-L1 and the ypT stage was also observed. Additionally, TC PD-L1– was correlated with significantly superior LRFS than PD-L1+ in these patients. Furthermore, to our knowledge, this is the first report regarding the different

PD-L1 expression between SCRT and LCRT in rectal cancer after neoadjuvant RT.

In accordance with the results mentioned earlier, PD-L1 protein expression and its correlation with disease outcome and prognostic value have been well demonstrated in various types of cancers, such as lung, ovarian, esophageal, and gastric, wherein TC PD-L1 was intensively associated with poor prognosis.^{13–16} In colorectal cancer, TC PD-L1 expression

was significantly high in mismatch repair-deficient tumors when compared with mismatch repair-proficient tumors, and patients with a high PD-L1 expression had significantly poor outcomes in both.^{17,18} In our study, a correlation between TC PD-L1– and improved LRFS was maintained in rectal cancer with neoadjuvant RT. Moreover, TC PD-L1– showed a predisposition toward improved DFS and OS. Our results also coincide with a previous study in rectal cancer

patients after neoadjuvant chemoradiotherapy.¹⁹ However, as a result of heterogeneity, the predictive value of PD-L1 was questioned.²⁰ One explanation of minimal predictive value might be that the tissue sample with PD-L1 negative might be distinct from other untested regions which were positive. Another explanation is the different cut point in different assays.

Furthermore, in our analysis, the high local recurrence rate was observed in those patients with TC PD-L1+. Several studies showed that tumor recurrence was related to the PD-L1 expression level. TC PD-L1 expression could inhibit the cytotoxic activity of CD8-positive T-cells and suppress production of T-cell interleukin-2 (IL-2),¹⁹ thereby further restraining T-cell proliferation and inducing T-cell

apoptosis.^{4,6} Hence, TCs escaped from immune cytotoxicity and therapeutic measures through the combination of PD-L1 and PD-1.⁹ This might be one of the reasons for tumor recurrence after treatment. Therefore, the ability of antitumor immunity by T-cells can be improved through the inhibition of PD-L1 expression.

TC PD-L1 expression was regulated by a series of signaling pathways and transcription factors.²¹ Our results showed

that the TC PD-L1 was different in patients with LCRT and SCRT, suggesting that TC PD-L1 expression might be regulated by modifying the RT regimen. Radiation is deemed to induce local inflammatory or anti-inflammatory response on account of dose and fractionation.^{22,23} The PD-1/PD-L1 pathway has been well studied in the context of immune modulation and radiation. The PD-L1 expression was demonstrated as an upregulation after radiation treatment, which

led to radioresistance.¹⁰ On the other hand, preclinical studies present a combination of PD-1/PD-L1 pathway inhibition and ionizing radiation in mouse models, which achieved an excellent local tumor control through enhancement of anti-cancer immune responses.^{11,12} In the clinical study on AT-3 mammary tumors,¹⁰ blockade of the PD-L1/PD-1 pathway is effective on the primary tumor site, as well as in generating abscopal responses.

In addition to the TCs, the pertinence between IC PD-L1 and the ypT stage was also observed in this study. A previous study showed that, as the important element of ICs, immune cells' PD-L1 was correlated with early stage and high infiltration of T-cells.²⁴ According to the pathologist, ICs contained a lot of lymphocytes in our study. Lymphocytes play a pivotal role in antitumor response, especially cytotoxic T lymphocytes. The favorable prognosis in colorectal

Note: Positive expression of PD-L1 in TCs was significantly associated with LRFS (**B**), and no significant difference was found between PD-L1 expression and DFS or OS (**A** and **C**).

Abbreviations: DFS, disease-free survival; OS, overall survival; PD-L1, programmed death-ligand 1; LRFS, local recurrence-free survival; programmed death-ligand 1; TC, tumor cell.

cancer was affected by the high density of tumor-infiltrating lymphocytes and lymphoid reactions.²⁵ However, no statistical significance was observed in patients' prognosis in our analysis. Further studies should focus on the impact of IC PD-L1 in rectal cancer.

Nevertheless, it should be noted that this study had not enrolled patients without neoadjuvant RT. Since the study was a retrospective analysis of small sample size, prospective data and a larger sample size are essential to confirm the results. Additional studies are imperative to determine the role of RT in the expression of PD-L1. Lastly, the information about the gene expression profile and signaling pathway in the current study was limited, which hindered further analysis.

Conclusion

We have identified that the TC PD-L1 might negatively relate to long-term prognosis in LARC receiving neoadjuvant RT and play a critical role in tumor recurrence. On the other hand, the different RT regimens could result in varied PD-L1 expression. These results further supplement the

immunological study in rectal cancer and may provide a new strategy in the adjuvant treatment of rectal cancer.
