Background: Preoperative anemia in surgical patients has been linked to increased rates of allogeneic blood transfusion (ABT) and associated adverse patient outcomes such as prolonged ventilation in intensive care, increased length of hospital stay, and infections. We conducted a multifaceted implementation for orthopedic surgeons to improve preoperative patient assessment of anemia and iron deficiency to reduce perioperative blood transfusions.

Materials and methods: Using a before-and-after study design of independent samples, we recruited a convenience sample of surgeons who performed primary total hip arthroplasty at 1 Australian private hospital. Our implementation intervention consisted of: executive support, interactive education, and peer-to-peer support to encourage adherence to the National Blood Authority's Patient Blood Management Program (PBMP) guidelines. We also used monthly reminders, e-learning access, and posters. Pre and post medical record audits evaluated preoperative blood tests, preoperative anemia, and number of blood units transfused between day of surgery until discharge. The primary outcome was an increase in the proportion of patients with preoperative blood tests undertaken prior to total hip arthroplasty surgery as recommended by the PBMP guidelines.

Results: Audits from 239 pre- and 263 postimplementation patients from 3 surgeons were conducted. Our primary outcome showed a significantly increased proportion of patients who had all the required preoperative tests postimplementation (0% to 94.6%; $P < 0.0001$). Administration of ABT significantly decreased (pre: 9.2%, $n=22$; post: 2.3%, $n=6$; $P=0.001$) as well as the standard 2 blood units transfused (pre: 73%, $n=16$; post: 17%, $n=1$; $P=0.022$). The time between preoperative tests and day of surgery increased from 16 to 20 days ($P < 0.0001$), allowing more time for physician's review of test results.

Conclusion: Our results demonstrated successful implementation of a targeted PBMP to improve preoperative assessment to diagnose and treat anemia and/or iron deficiency prior to orthopedic surgery. This avoided unnecessary ABT and therefore mitigated potential risk to the patient.

Introduction

Preoperative anemia (hemoglobin [Hb] level of <130 g/L in men and <120 g/L in women)^{1,2} is present in approximately 30% of noncardiac surgical patients.³ It is associated with increased allogeneic blood transfusion (ABT) rates, prolonged ventilation in intensive care, increased length of hospital stay, and infection.³⁻⁸ The prevalence of preoperative anemia increases with age,⁹ contributing to significant morbidity and poor

functional outcomes for older surgical patients in particular.⁶ Absolute or functional iron deficiency (ferritin level of <100 µg/L or between 100 µg/L and 299 µg/L if the transferrin saturation is <20%)^{10–12} and/or chronic inflammation are the most common causes of preoperative anemia.¹³

There is a plethora of literature that describes the incidence of anemia in preoperative surgical patients as well as the link between anemia, ABT, and adverse outcomes.^{4,5,7,14} Current transfusion practices include liberal or restrictive strategies based on thresholds of hemoglobin of 10 g/dL or 8 g/dL, respectively. Liberal strategies have not been found to be superior to restrictive strategies,^{15–17} and some have shown worse patient outcomes, such as cardiac events, pneumonia, thromboembolism, and infections.^{18,19} Therefore, restrictive strategies have been the recommended approach when a blood transfusion is necessary to treat anemia, and as a conservative measure in the use and management of blood products.

The need to conserve blood and reduce waste has been driven by the increasing aging population, cost of “fresh” blood products, and adverse events associated with transfusions.⁸ In 2012 in Australia, the National Safety and Quality Health Service Standards were released.²⁰ Standard 7 (Blood and Blood Products) specifically advocated for a safe and efficient use of blood products as a scarce resource. In addition, the new Australian Patient Blood Management (PBM) Guidelines (Module 2: Perioperative) was also published in 2012 containing 22 evidence-based recommendations and 20 practice points supporting the new standard of care to identify, evaluate, and manage preoperative anemia.²¹ The recommendation of the PBM guidelines is to perform preoperative tests comprised of: a full blood count, full iron studies (including ferritin), C-reactive protein, and renal function studies (including urea, creatinine, and electrolytes). These tests form the baseline assessment for perioperative care in which abnormal blood results should encourage physicians’ review and treatment in the case of anemia, iron deficiency, and renal impairment.

The impetus for implementing a Patient Blood Management Program (PBMP) in our study was contributed to by 2 additional issues. First, a 2013 hospital-wide accreditation recommended that patients with low hemoglobin should be identified earlier and managed appropriately. Second, a 2012 retrospective medical record audit of primary total hip arthroplasty patients (n=383) conducted between July and December 2011 indicated 21% (n=79) of patients received an ABT, of whom 35% (n=28) of the 79 patients were clinically anemic preoperatively resulting in 87% (n=69) of patients

with 2 or more units of ABT. The argument for a PBMP is compelling and is advantageous for patients and hospitals alike.²² However, the effectiveness of achieving a change in long-standing practices involves changing perception and long-held behavior by clinicians.²³ Our implementation at an Australian private hospital aimed to improve adherence of orthopedic surgeons to the PBM guidelines to evaluate and manage preoperative anemia 0–28 days prior to surgery, thereby increasing the proportion of patients with a complete set of preoperative tests prior to total hip arthroplasty surgery.

Materials and methods

Using a before-and-after design with independent samples, this study was conducted at 1 private metropolitan hospital in Sydney, Australia. This hospital was ideally placed to adopt a PBMP as it was a center that performed in excess of 2,000 total joint arthroplasties per year.

Sampling and recruitment

Eligible surgeons were those who performed >100 primary unilateral total hip arthroplasties each year as they were regarded to represent the patient population due to their high volume of surgical patients. Eligible surgeons and their usual anesthetists were invited by e-mail to attend a 1 hour study launch and education session presented by a specialist physician and the principal investigator. The launch outlined key messages of the PBMP (Box 1) and was convened by a specialist nephrologist with a special interest in the PBMP and was co-hosted by the Hospital Chief Executive. Following this presentation, the surgeons were visited in their consulting rooms by the principal investigator who provided the information sheet and asked for their signed consent to participate in the study.

The medical records of patients who had undergone a primary unilateral total hip arthroplasty procedure under one of the eligible participating surgeons were included. Medical records of patients who had undergone emergency surgery, bilateral or revision surgery, and those who had previously had surgery on the other hip during our preimplementation phase were excluded from the study. Patient consent was not required as this retrospective audit was considered to be part of standard hospital reporting practices. Ethical approval was obtained from St Vincent’s Hospital, Darlinghurst Human Research Ethics Committee.

Intervention

The intervention was conducted from October 2014 until June 2015 (Box 2) and entailed the following: 1) executive

Box 1 National Blood Authority, Australia, Patient Blood Management Guidelines: Module 2 – Perioperative 2012

Preoperative phase: All patients to have preoperative full blood count to examine hemoglobin levels, full iron tests (including ferritin and transferrin saturation), C-reactive protein, and renal function tests (urea and creatinine) added to their standard preoperative blood tests up to 28 days preoperatively.

Anemia (hemoglobin level of <130 g/L in men and <120 g/L in women) and low iron stores (ferritin level of <100 µg/L) to be treated with iron replacement prior to surgery (either oral iron in divided daily doses, or intravenous iron if oral iron not tolerated or effective or where rapid iron repletion is required ie, <2 months to nondeferrable surgery) as indicated by the National Blood Authority's preoperative algorithm.

As serum ferritin is an acute-phase reactant, it is important to examine both ferritin and transferrin saturation levels to determine the level of iron stores.

Postoperative phase: Patients are not to receive a blood transfusion when the hemoglobin level is ≥100 g/L in the postoperative period from day of surgery until discharge on day 5–7 of the acute postoperative period.

Patients with postoperative anemia should be assessed based on the patient's clinical status and not on a hemoglobin 'trigger' alone. If a transfusion is deemed necessary, then 1 unit of blood is to be administered and the patient reassessed to examine response prior to further transfusion.

Note: Data from the National Blood Authority.²¹

Box 2 PBMP implementation**Executive support**

The Chief Executive Officer of the hospital opened the project launch.

Interactive education

A specialist physician and the CEO of the hospital launched the project and presented the key PBMP messages to surgeons during a 30-minute presentation.

Orthopedic ward nurses and pre-admission clinic nurses were also informed of the implementation project and attended a single 15-minute educational session outlining PBM aims and outcome measures. Nursing education was supported by Blood Safe e-learning module – Patient Blood Management located on the hospital's intranet.

Peer to peer support

Specialist physician was available by telephone call or email to provide expert clinical advice concerning blood results and treatment.

Principal investigator made daily visits to pre-admission staff to encourage interpretation of blood results emphasising anemia and iron deficiency markers and encouragement to contact the relevant surgeon.

Email and poster reminders

Official National Blood Authority posters were placed in the stairwell and treatment rooms. These posters were changed monthly and communicated key messages such as single unit transfusion and dispelling myths about blood safety, improved healing and no associated cost with blood transfusion.

Monthly short targeted emails were sent to participating surgeons to remind them of the key points from the launch (Box 3), guidelines and relevant articles.

Audit feedback mechanism

Half way through the implementation phase an audit and feedback was conducted and reported back to the surgeons.

Abbreviations: CEO, Chief Executive Officer; PBMP, Patient Blood Management Program.

support from the Chief Executive Officer of the hospital who launched the project; 2) 1 interactive education session for surgeons/anesthetists and 1 for nurses conducted by the principal investigator focusing on outlining the key messages from the PBM guidelines; 3) peer-to-peer support to surgeons via telephone by the specialist physician; 4) 1 audit and feedback conducted midway through the implementation to maintain and encourage guideline compliance; and

5) monthly e-mail reminders and relevant articles sent to participating surgeons (Box 3). Other steps of the implementation included placement of Blood Watch posters, which is a state-wide transfusion practice improvement program supported by the Department of Health.²⁴

The implementation targeted orthopedic surgeons. However, ward and preadmission clinic nurses were also invited to attend 1 education session with the rationale that they

Box 3 Content of monthly reminder emails

1. Blood tests including full blood count, full iron tests, C-reactive protein, electrolytes/urea/creatinine should preferably be performed at least 28 days pre-op. Please “copy” the results to the general practitioner, whatever physician is involved in the patient’s care, and the hospital’s preadmission clinic.
2. It is never too late – ideally iron infusions should be administered at least 3 weeks prior to surgery but may provide clinically significant benefit even if administered in the days prior to surgery.
3. Consider referral to the preadmission clinic at least 4 weeks pre-op whenever possible.
4. Patients with stable cardiovascular disease do not necessarily need to have their hemoglobin “topped up” above 80 g/L. In fact, they may benefit more from an iron infusion if clinically indicated.
5. In the rare instances where a blood transfusion is considered absolutely necessary, transfuse a single unit and repeat the full blood count.

could guide, influence, and prompt surgeon and/or anesthetist compliance with guidelines by instigating preoperative iron replacement when necessary. While anesthetists also attended the initial education session, there was no further face-to-face contact with anesthetists.

Data collection

Retrospective audits of medical records from patients of consenting orthopedic surgeons were performed between July to December 2012 and July to December 2015 for the pre-implementation and postimplementation audit, respectively. Patient names were obtained from preadmission clinic. Both medical record audits used identical tools and methods and were collected by the primary researcher. Audit data provided to surgeons were deidentified and aggregated.

Outcome measures

The primary outcome measure was the number of patients who 0–28 days prior to total hip arthroplasty surgery had all of the following preoperative blood tests: 1) full blood count, 2) full iron studies, including ferritin and transferrin saturation, 3) C-reactive protein, 4) renal function studies, including urea, creatinine, and electrolytes.

Secondary outcome measures were 1) the number of ABTs administered between the day of surgery and postoperative day 7 (or day of discharge – whichever came first), 2) the time between ordering the preoperative tests and day of surgery (in days), 3) the level of anemia as defined by the World Health Organization definition (hemoglobin <130 g/L in men and <120 g/L in women), 4) iron deficiency defined as a ferritin <100 µg per liter or between 100 and 299 µg per liter if the transferrin saturation is <20% in the 0–28 days prior to day of surgery, 5) the number of preoperative iron infusions related to low ferritin and transferrin saturation, and 6) the administration of tranexamic acid (antifibrinolytic proven to reduce a patient’s perioperative blood loss).

Instrument

The following data were collected using a piloted form: 1) patient characteristics; 2) laboratory results; 3) clinical treatment; 4) surgery details; 5) and postoperative treatment. In the patient characteristics section age, gender, admission, and discharge dates were recorded. Preoperative laboratory results were obtained from both the medical records and access to the online pathology service. The number of days between the preoperative tests and the booked surgery date was recorded. The preoperative tests comprised: full blood count, full iron studies (including ferritin and transferrin saturation), C-reactive protein, and renal function studies (including urea, creatinine, and electrolytes count). In the clinical treatment section of the instrument, we recorded the administration of a preoperative iron infusion. Surgery details collected were surgery date, the use of tranexamic acid (Yes/No), and the American Society of Anesthesiologists score (ASA) completed by the anesthetist prior to induction.²⁵ Finally, the postoperative treatment data collected included the number of ABT units and, where relevant, the postoperative day of transfusion.

Data analysis

Data were analyzed using SPSS version (IBM SPSS Statistics 23, IBM Corporation, Armonk, NY, USA). The proportion of patients who had all 4 preoperative blood tests performed was calculated. The categorical and continuous data were summarized as descriptive statistics. Pre- and postimplementation differences for patient characteristics, preoperative blood tests, anemic patients with ABT and use of tranexamic acid were examined using χ^2 tests or Fisher’s exact test as appropriate. Independent sample *t*-test was used to examine mean differences of time between the ordering day of the preoperative tests and the day of surgery in the pre- and postimplementation groups. The *P*-value for the statistical significance was set at <0.05.

Results

All 3 eligible orthopedic surgeons agreed to participate in the study. A total of 239 medical records of patients undergoing primary total hip arthroplasty were audited for the preimplementation phase and 263 for the postimplementation phase. All patients' medical records from participating surgeons in the preimplementation group met the inclusion criteria. In the postimplementation phase, there were 2 patients who were excluded: 1 was an emergency fracture and the other patient had a unilateral hip and knee replacement concurrently. There were 64% (n=154) females in the preimplementation phase and 58% (n=151) in the postimplementation phase. The most common age group was 61–80 years old, with 61% (n=145) in the preimplementation and 70% (n=183) in the postimplementation phase (Table 1). The overall health status of patients was inferred by the ASA score. The ASA showed that the highest rating assessment was ASA 2 (pre: 47%, n=113; post: 40%, n=105; $P=0.19$) indicating that most patients in both groups were relatively healthy. The only significant difference between groups was for the ASA

3 score (ie, severe systemic disease), but this was seen only in 11% of patients from the preimplementation and 20% of patients from the postimplementation ($P=0.003$; Table 1).

Primary outcome

There was a significant increase in the number of patients who 0–28 days prior to total hip arthroplasty surgery had all preoperative tests performed following our intervention (95%; n=247, $P<0.0001$), compared to none in the preimplementation group (Table 2). Of these preoperative tests, over 98% of patients in both pre- and postimplementation group had a full blood count and renal function studies performed. However, significant increases were observed from pre- (n=1, 0.4%) to postimplementation (n=254, 97%) in the number of patients who had full iron studies ($P<0.0001$) and a C-reactive protein test (pre: n=132, 55%; post: n=245, 94%; $P<0.0001$). Time (days) between the preoperative tests and the date of surgery significantly increased from 16 to 20 days following the implementation ($P<0.0001$, Table 2).

Table 1 Patient demographics

Time (days) preoperative blood sample obtained to day of surgery (mean)	16 (days)	20 (days)	<0.0001*

Notes: *P-value significant <0.05; ^aFisher's exact test.

Secondary outcomes

The levels of preoperative anemia were not significantly different between the pre- and postimplementation group ($P=0.224$) (Table 3). However, there was a significant decrease of ABT postoperatively (pre: 9.2%, $n=22$ and post: 2.3%, $n=6$; $P<0.001$). Of those patients who received an ABT, there was a significant increase in the number of patients receiving only a single unit of blood as per the guidelines following the implementation ($P<0.003$). Iron infusions were not given to any of the patients in the preimplementation group compared to 4.5% ($n=12$) in the postimplementation group prior to surgery ($P=0.001$). The use of tranexamic acid improved significantly following implementation (pre: 65%, $n=155$; post: 93%, $n=242$; $P<0.0001$) (Table 3).

Discussion

Our results showed that significantly more patients were treated according to the PBMP guidelines in undergoing all the required preoperative blood tests following our implementation strategy. The postimplementation group received a more rigorous preoperative assessment, resulting in increased administration of iron infusions for severely iron deficient patients and therefore avoiding the habitual approach of unnecessary ABT.^{26,27} In addition, there was a significant increase in the rates of single-unit transfusions and a corresponding decrease in 2-unit transfusions when compared to the preimplementation group. Single-unit transfusion practice is an integral component of a PBMP, as

it decreases waste and risk associated with transfusions from multiple donors. In comparison, transfusions using 2 units of blood have often been a default decision without supportive empirical data, noncognizant of the risks versus the benefit.²⁴ In addition, the significant increase postimplementation in the use of antifibrinolytic agents such as tranexamic acid may have also contributed to the decrease in ABT due to their effects of reduction in blood loss and higher postoperative hemoglobin.²⁸ These results are notable despite the significant number of patients with an ASA 3 score (severe systemic disease) in the postimplementation group compared to the preimplementation group, demonstrating the benefits of changing clinician behavior when treating patients with known comorbidities.

For those patients identified as anemic and/or iron deficient, iron infusions were advocated instead of iron taken orally, as per the guidelines for those whose surgery is to commence within 2 months. Iron infusions are a more effective treatment for iron deficiency anemia because they correct levels more quickly than oral iron.^{10,29,30} The iron infusion can take effect between 2 and 6 weeks compared to oral intake that can require on average 6 weeks.³¹ Consequently, as our primary outcome was only relevant to patients 0–28 days prior to surgery, we did not collect data on the number of patients taking oral iron. Patients in the preimplementation group could not be identified as iron deficient due to lack of routine iron studies testing undertaken at that time. Therefore, none of the preimplementation group patients received an infusion

Table 3 Patient preoperative diagnosis of anemia and iron deficiency and postoperative management

Abbreviations: ABT, allogenic blood transfusion; N/A, not applicable.

prior to surgery. That a significant increase of 4 days between the preoperative blood tests to day of surgery was observed is of note. This increase postimplementation allowed more time for further assessment of patients for anemia and/or iron deficiency and for treatment with iron infusion prior to surgery. It is possible some of these infusions also may have been ordered by the anesthetist (and not necessarily the surgeon) at the time of the preadmission clinic.

A limitation of our study is the time frame between audits. Prior to the PBM guidelines release at the end of 2012, awareness of blood management among hospital clinicians was poor. Therefore, the decision for our study was to use the final 6 months of 2012 with the rationale that staff would be relatively untainted from the release of the PBM guidelines. This resulted in the time frame gap that is observed between the medical record audits for the pre- and postimplementation. We also did not collect data on the cost-effectiveness of our intervention, which was beyond the scope of our study.

The inherent challenges of implementation in a private hospital setting are of note. Australia has a growing private hospital sector operating alongside public hospitals. Private hospitals allow the medical practitioners more autonomy.³² Therefore, private hospitals must balance the introduction of best practice guidelines without dictating this to medical staff. The preadmission clinic has a rapid flow of patients which discourages analytical review of pathology test results. The difficulty of obtaining a medical order in the private system and the potential for adverse side effects were contributing factors in the hesitation to prescribe an iron infusion. Although orthopedic surgeons at the hospital were aware of the advantages of meticulous surgical care and tranexamic acid use to reduce blood loss, they were less convinced about the importance of managing preoperative anemia and iron deficiency. Hence, although challenging, we successfully modified the surgeons' views that a PBMP would be beneficial for their medical reputation and better outcomes for their patients. To the best of our knowledge, this is one of the first published studies implementing the PBM guidelines in a private hospital setting in Australia.

Conclusion

Our results demonstrated that programs to implement guidelines can be built into the current processes of care and can improve patient outcomes. Our study is one of the few to provide evidence of the effectiveness of a targeted implementation to improve early assessment and preoperative management of anemia and/or iron deficiency in a private hospital setting. Other hospitals should consider replicating

our intervention to better manage postoperative anemia and reduce the associated inherent risks of blood transfusions and conserving this limited resource.

Journal of Blood Medicine

Publish your work in this journal

The Journal of Blood Medicine is an international, peer-reviewed, open access, online journal publishing laboratory, experimental and clinical aspects of all aspect pertaining to blood based medicine including but not limited to: Transfusion Medicine; Blood collection, Donor issues, Transmittable diseases, and Blood banking logistics; Immunohematology; Artificial and alternative

Submit your manuscript here: <http://www.dovepress.com/journal-of-blood-medicine-journal>

Dovepress

blood based therapeutics; Hematology; Biotechnology/nanotechnology of blood related medicine; Legal aspects of blood medicine; Historical perspectives. The manuscript management system is completely online and includes a very quick and fair peer-review system. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
