Purpose: Nanotechnology applied to cancer treatment is a growing area of research in nanomedicine with magnetic nanoparticle-mediated anti-cancer drug delivery systems offering least possible side effects. To that end, both structural and chemical properties of commercial cobalt metal nanoparticles were studied using label-free confocal Raman spectroscopy.

Materials and Methods: Crystal structure and morphology of cobalt nanoparticles were studied by XRD and TEM. Magnetic properties were studied with SQUID and PPMS. Confocal Raman microscopy has high spatial resolution and compositional sensitivity. It, therefore, serves as a label-free tool to trace nanoparticles within cells and investigate the interaction between coating-free cobalt metal nanoparticles and cancer cells. The toxicity of cobalt nanoparticles against human cells was assessed by MTT assay.

Results: Superparamagnetic Co metal nanoparticle uptake by MCF7 and HCT116 cancer cells and DPSC mesenchymal stem cells was investigated by confocal Raman microscopy. The Raman nanoparticle signature also allowed accurate detection of the nanoparticle within the cell without labelling. A rapid uptake of the cobalt nanoparticles followed by rapid apoptosis was observed. Their low cytotoxicity, assessed by means of MTT assay against human embryonic kidney (HEK) cells, makes them promising candidates for the development of targeted therapies. Moreover, under a laser irradiation of 20mW with a wavelength of 532nm, it is possible to bring about local heating leading to combustion of the cobalt metal nanoparticles within cells, whereupon opening new routes for cancer phototherapy.

Conclusion: Label-free confocal Raman spectroscopy enables accurately localizing the Co metal nanoparticles in cellular environments. The interaction between the surfactant-free cobalt metal nanoparticles and cancer cells was investigated. The facile endocytosis in cancer cells shows that these nanoparticles have potential in engendering their apoptosis. This preliminary study demonstrates the feasibility and relevance of cobalt nanomaterials for applications in nanomedicine such as phototherapy, hyperthermia or stem cell delivery.

Keywords: Raman spectroscopy, cobalt nanoparticles, cancer cells, stem cells, cellular uptake, apoptosis, label-free tool

Introduction

During the last decades, due to the constant demand of more efficient and smaller devices, metal nanoparticles (MNPs) have attracted considerable attention.^{1,2} The main interest in MNPs comes from their unique chemical and electronic properties arising from their high surface to volume ratio. Magnetic nanoparticles are also attracting a lot of interest as size reduction further affects their magnetic properties. Therefore, MNPs with dimensions smaller than the characteristic dimensions of a single magnetic domain are of more particular interest. As a consequence, such

Correspondence: Erwan Rauwel
Email erwan.rauwel@emu.ee

NPs exhibit superparamagnetism (SPM) and exhibit zero coercive field and remanence,^{3,4} thereby making them the best candidates for developing applications in emerging areas like nanomedicine and more particularly in theranostics.⁵⁻⁷ The development of nanotechnologies during the last ten years has had a positive impact on several applications in a plethora of fields viz., nanomedicine^{8,9} for magnetic hyperthermia,^{10,11} cancer^{12,13} and orthopedics.¹⁴ Nanotheranostics,¹⁵ which combine both therapeutic and diagnostic capabilities at the nanoscale, have broadened the perspectives of personalized medicine.^{16,17} Other targeted applications in the field of nanomedicine have also been investigated, such as photo-diagnostic and photothermal anticancer therapy (PTT) using platinum nanoparticles¹⁸ or gold nanoparticles,¹⁹⁻²¹ as well as nano-loaded stem cell delivery.²² Moreover, cancer nanotechnology is a fast growing area of research in nanomedicine mainly because systemic application of anticancer drugs has certain drawbacks with regards to side-effects, non-effective drug concentration at the target area and its en-route degradation.²³ In that regard, magnetic nanoparticle-mediated anti-cancer drug delivery systems offer added advantages, such as minimized side effects, along with a better control for drug delivery. Therefore, researchers are actively exploring these properties^{24,25} by investigating the interaction between the cell membrane and nanoparticles, which has been the focus of multiple studies.²⁶ In fact, different cellular uptake modes can occur and require further understanding in order to develop a suitable treatment. Additionally, the toxicity of metal nanoparticles involved in such uptakes also requires assessment before integrating these nanomaterials into cancer treatment applications.

Raman spectroscopy is a non-invasive method of analysis based on biochemical mapping of the analysed sample area. This technique provides specific information on the unique vibrations of molecules after excitation with a monochromatic laser. Confocal Raman microscopy with its high spatial resolution and unique compositional sensitivity is used as a unique label-free tool to trace drugs and nanoparticles within cells.²⁷⁻³¹ The cells and their components are analysed via their vibrational spectra owing to differences in their biochemical compositions. The Raman nanoparticle signature therefore enables precise nanoparticle detection in the cell without any labeling.^{27-29,32} By applying this method, the uptake of Co MNPs by cancer cells and their localization within were investigated.

The Co MNPs are renowned catalysts, more particularly in Fischer-Tropsch reactions.³³ Reports on Co MNPs investigated for biomedical applications (or in biomedicine) are very scarce and most of the investigations have mainly been carried out with cobalt metal oxide nanoparticles^{34,35} due to the intrinsic pyrophoric properties of Co MNPs. In general, Co MNPs have to be coated with an oxide layer, a carbon or an organic layer in order to suppress their violent and spontaneous oxidation on exposure to air.³⁶ Furthermore, Co MNPs with sizes under 8nm exhibit superparamagnetic properties,^{37,38} along with a high magnetic saturation, thus making them promising nanomaterials towards applications in emerging areas like nanomedicine and water purification. Therefore, ultra-stable non-pyrophoric Co MNPs are necessary for the development of practicable applications. The surfactant-free Co MNPs used for this study did not exhibit any pyrophoric behaviour, which made studying their cell-penetrating abilities against cancer cells achievable.

In this study, we have investigated the interaction between cobalt metal nanoparticles and cancer cells using Raman spectroscopy as a label-free tool to investigate the development of alternate cancer treatment routes.

Materials and Methods

Cobalt Metal Nanoparticles

Cobalt metal nanoparticles are of industrial grade and have been provided by PRO-1 NANOSolutions in the form of a black powder. Before utilization, the Co nanoparticles were dispersed in PBS buffer solution through energetic shaking and then sonicated for 5 minutes in an ultrasonic bath.

Cell Lines

The following cell lines were used: MCF-7 (ATCC HTB-22), HCT 116 (ATCC CCL-247), HEK 293 (ATCC CRL-1573), and PPC-1 (ATCC HTB-190). Furthermore, primary mesenchymal stem cells derived from the dental pulp (DPSC) were tested.^{27-29,32} DPSCs were obtained from human wisdom teeth, extracted for orthodontic reasons and recovered from healthy patients (age range: 15-18 years). Written informed consent was obtained from the patients' parents as approved by the local ethical committee (Comité de Protection des Personnes, Montpellier hospital, France). DPSCs were isolated and characterized as previously described.²⁹ Cancer cell lines and primary mesenchymal stem cells were grown in DMEM and

α MEM media, respectively (Dulbecco's and Alpha Modified Eagle's Medium) containing 10% FBS and 1% antibiotics (100 $\mu\text{g}\cdot\text{mL}^{-1}$ penicillin Streptomycin) at 37°C and 5% CO_2 .

PBS Buffer Solution

PBS buffer solution is composed of 1L of distilled water in which 8g of NaCl, 0.2g of KCl, 1.44g of Na_2HPO_4 and 0.24g of KH_2PO_4 were added. The pH of the solution was adjusted to 7.4 by addition of HCl.

Structural Study

X-ray diffraction (XRD) patterns were collected using a Panalytical Empyrean diffractometer with a Cu K α radiation source ($\lambda = 0.15406\text{nm}$). CHN measurement was carried out on Leco Truspec Micro CHNS Analyzer model 630–200–200, at temperature of 1075°C. Carbon, hydrogen and sulphur were measured by infrared absorption and nitrogen was measured by thermal conductivity.

Morphological Study

High-resolution transmission electron microscopy (HRTEM) was carried out on 80–300 FEI Titan, operating at 300 kV, disposing a point to point resolution of 1.4Å.

Magnetic Measurements

Magnetic measurements were performed using a Quantum Design MPMS3 SQUID magnetometer, using its VSM measurement option, at 300K, using magnetic fields ranging from –70 and +70 kOe. The remnant magnetic fields of the superconducting magnet used as the magnetic field source (about 22Oe after reaching 70kOe) were considered during the estimation of the coercive field.

Raman Spectroscopy

Raman spectra were collected using a WITec Confocal Raman Microscope System alpha 300R (WITec Inc., Ulm, Germany). Excitation in confocal Raman microscopy is generated by a frequency-doubled Nd:YAG laser (New-port, Irvine, CA, USA) at a wavelength of 532nm, with 50mW maximum laser output power in a single longitudinal mode. The incident laser beam is focused onto the sample through a 60 \times NIKON water immersion objective having a numerical aperture of 1.0 with a working distance of 2.8mm (Nikon, Tokyo, Japan). The laser power after the objective is 15mW but the power absorbed by cells in PBS is lower.

The spatial and depth resolutions are 300nm and 1 μm , respectively. The mixed scattered radiation passes through

an edge filter to block the Rayleigh radiation from the Raman signal, which is then directed to the electron multiplying charge coupled device camera EMCCD (DU 970N-BV353, Andor, Hartford, USA). The electron multiplying charge coupled device chip size was 1600 \times 200 pixels, the camera controller was a 16-bit A/D converter operating at 2.5MHz. The acquisition time of a single spectrum was set to 0.5 sec. An area of 150 \times 150 points per image was recorded leading to the acquisition of 22500 spectra for one image. The advantage of our analysis method using EMCCD (Electron multiplying CCD) is the high speed of scan. Each pixel can be recorded with a very good signal-to-noise ratio at low integration times. For the high spatial resolution of the system (300nm), a complete image of a whole cell is recorded for a better analysis. Data acquisition and processing were performed using Image Plus 5.2 software (Ulm, Germany) from WITec.

The analysis is based on two methods. The first method provides integrated Raman intensities in specific regions in particular C-H stretching modes. The integrated Raman intensities of C-H stretching mode (2800–3000 cm^{-1}) represent the lipid-protein distribution in the cells. Data processing is performed using Image Plus software from WITec. Each image regarding these integrated intensities could provide a map of the region. Using a color-coded reference table, bright yellow hues indicate the highest intensities while orange hues the lowest integrated intensities of the chosen region. The second analysis method is the K-mean cluster analysis (KMCA), which separates data into k-mutually exclusive clusters and can run multiple times. KMCA was realized using the WITec Project Plus software.

For Raman experiments, 2x10⁵ MCF7 cells were cultivated for 24h onto polished and disinfected calcium fluoride CaF_2 (Crystran Ltd, Dorset, UK) substrates in 35mm petri dishes. Nanoparticles were suspended in pure distilled deionized water. The dissolved nanoparticle solution was then added to the cell culture medium at 2 $\mu\text{g}/\text{mL}$ concentration for 1-hour incubation. The CaF_2 substrates with adhered cells are fixed with 2% PFA (paraformaldehyde) after thorough rinsing with 1x PBS. Cells were kept in 5mL PBS and transferred directly for Raman measurements.

Toxicity Study

Cytotoxicity of different concentrations of cobalt nanoparticles was assessed via MTT assay. Human embryonic kidney (HEK) or PPC-1 cells were seeded on day 0 at

a density of 1000 per well in 96 well microtiter plates. On day 1, cobalt nanoparticles at different concentrations were added. After a 24 h incubation period, the medium containing nanoparticles were removed from the plate to ensure that no nanoparticles remain in the solution and avoid overlapping or hinder MTT assay. After 24 h, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) was added to each well (0.5mg/mL; Sigma-Aldrich) and plates were maintained at 37°C for 2 hours. The medium was then discarded; DMSO was added to each well to lyse the cells. Absorbance was measured at 530nm using a multiwall spectrophotometer (Tecan, microplate reader). All MTT assays were repeated twice.

Results and Discussion

Morphological Characterizations

In **Figure 1A**, the X-ray diffraction pattern obtained from the Co nanopowder shows that cobalt nanoparticles are highly crystalline with a face-centered cubic (Fm3m) crystal structure ($a = 3.5447\text{\AA}$) and a crystallite average diameter of 2.5nm (JCPDS 15–806).³⁹ The $\langle 111 \rangle$, $\langle 200 \rangle$ and $\langle 220 \rangle$ diffraction peaks are in good agreement with the crystalline cubic Co metal (PDF No. 79–1770).³⁹

The TEM micrographs of **Figure 1B** and **C** provide an overview of the cobalt metal nanoparticles investigated in this study. In **Figure 1B**, some of the Co MNPs are spherical and monodispersed on the carbon-coated grid used

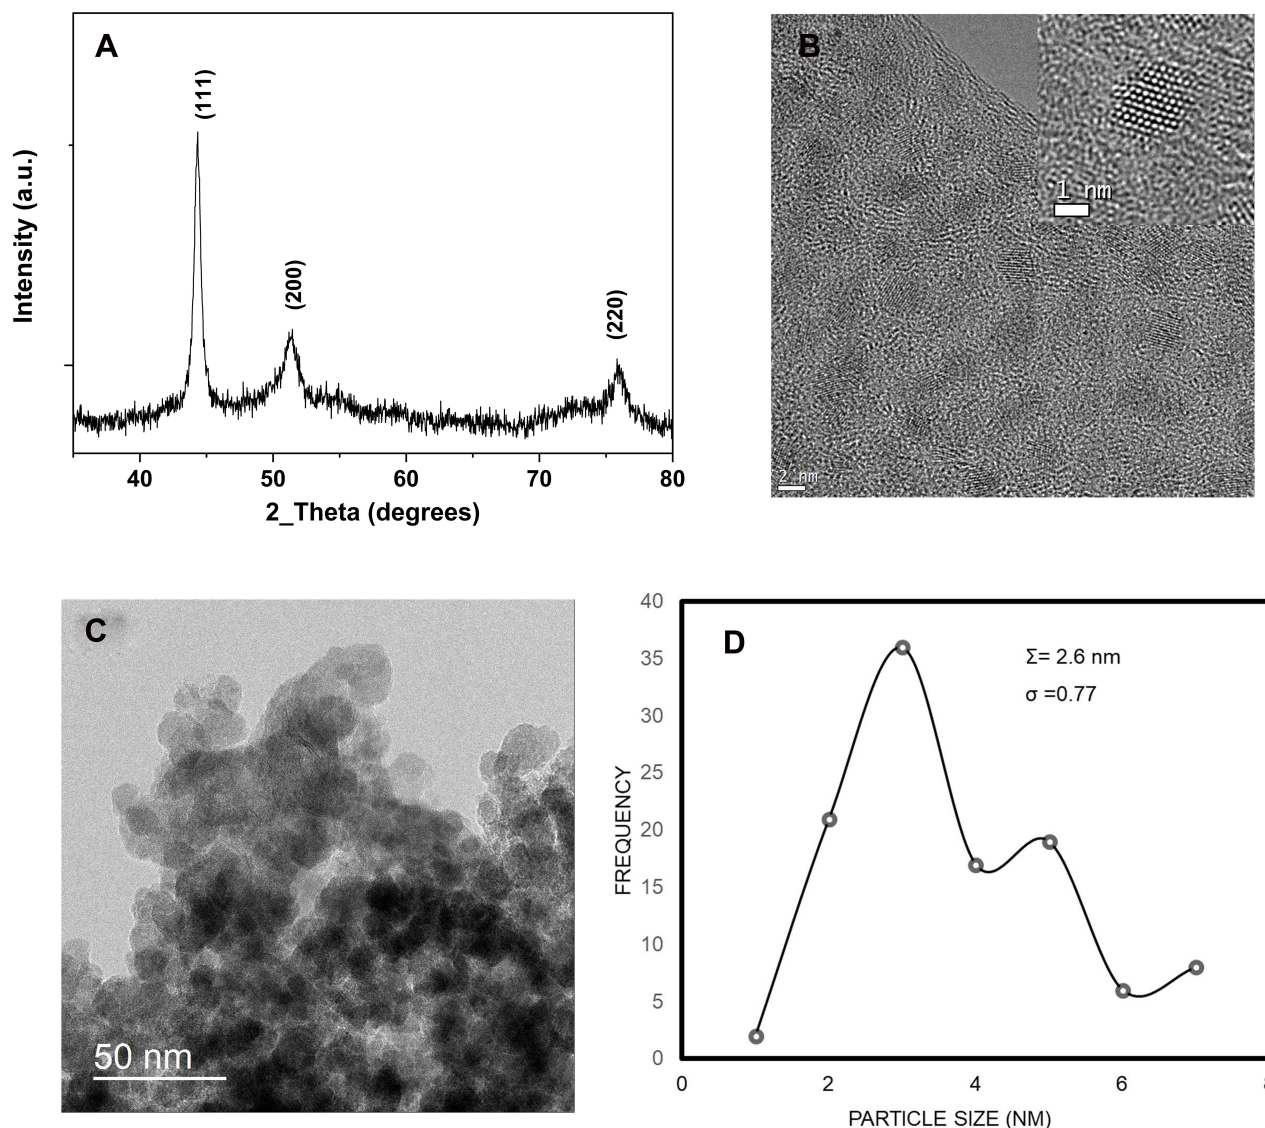

Figure 1 (A) XRD pattern of Co metal nanoparticles used in the study, (B) high-resolution overview of cubic Co metal nanoparticles of 5nm diameter, inset is a high-resolution TEM image of one cobalt nanoparticle (C) low magnification TEM overview of cubic Co metal nanoparticles agglomerated, (D) size distribution histogram.

for TEM observation. They are all crystalline as observed from the lattice fringes on the same image. In the inset, a high-resolution micrograph of one highly crystalline nanoparticle is provided. The nanoparticle is oriented in the $\langle 110 \rangle$ direction as indicated by the point-to-point resolution of the atomic columns. Contrary to Figure 1B, some of the Co nanoparticles in Figure 1C tend to agglomerate into larger clusters mainly because they are surfactant free. The size distribution histogram in Figure 1D provides a mean nanoparticles size of 2.6nm with a low standard deviation of 0.77.

The cleanliness of the Co MNPs surfaces and the detection of surfactants or organic species were investigated using carbon-hydrogen-nitrogen (CHN) measurements. After analysing 2.218mg of Co MNPs, 0.451 weight% of carbon and 0.239 weight% of nitrogen was obtained; neither hydrogen nor sulphur was detected. This analysis suggests that carbon and nitrogen detected are mainly due to exposure to air. In addition, since there is no organic coating on the surface of the Co MNPs, therefore, the effect of direct interaction of Co MNPs with cancer cells can be straightforwardly evaluated.

Magnetic Properties

The magnetic properties of the Co nanoparticles were investigated and the magnetic field dependence magnetization (M-H) hysteresis loop at 300K was measured. A typical M-H loop measured at 300K, and normalized to the Co mass content, is presented in Figure 2. The M-H curve at 300K displays a saturation magnetization at around 5kOe

Figure 2 M-H hysteresis loop measured at 300K for Co nanoparticles, inset shows the details of the measurement around the origin.

with an estimated coercivity $H_C < 76\text{Oe}$ (inset of Figure 2). The saturation magnetization (MS) at 300K is $160.4\text{e.m.u./g}_{\text{Co}}$, which is comparable to the theoretical value of the saturation magnetization of $163\text{e.m.u./g}_{\text{Co}}$ for Co metal.^{37,40,41} This further confirms that the major content (>90%) of our samples is metallic cobalt. The investigations of the magnetic properties of the Co nanomaterials reveal that the Co MNPs exhibit a mixture of superparamagnetic and a soft ferromagnetic behaviour.

Raman Spectra Study

In order to study the interaction between Co MNPs and MCF7 breast cancer cells, the Raman scattered light from free-standing Co MNPs was analysed. Figure 3A and B are the optical images of the Co MNPs analysed by Raman spectroscopy. The two Raman patterns (calculated as average spectra) obtained at low and high laser power 5mW and 20mW, respectively (Figure 3C) were also compared. The Co MNPs spectrum is characterized by three main peaks centred at 474, 512, 608 and 680cm^{-1} . These peaks correspond to the E_g , F_{2g}^1 , F_{2g}^2 , and A_1 modes of single-crystal Co_3O_4 .^{42,43}

Although the laser power is less than 20mW, it is nevertheless sufficient for spontaneous combustion of the Co nanoparticles to occur (Figure 3B). This could be attributed to the absence of organic coating on their surfaces. Under low laser power, the Raman pattern corresponds to face-centred cubic cobalt metal as illustrated by the blue spectrum in figure 3c.^{44,45} The Raman pattern in Figure 3C (red spectrum) corresponds to the Co_3O_4 crystalline structure. Consequently, it confirms that the laser irradiation provokes the spontaneous oxidation of the Co MNPs. Therefore, the laser power was reduced to less than 5mW during the study. The Raman spectrum at low energy served as a reference for the identification of free-standing Co MNPs in the PBS solution. Co MNP were stabilized in the DMEM medium containing MCF7 breast cancer cells for 1 hour, which was sufficient to bring about the diffusion of nanoparticles within the MCF7 breast cancer cells.

Raman spectroscopy enables identifying two different signals from the Co MNPs. In Figure 4, the blue spectrum pertains to the extracellular nanoparticle signature, as the C-H group belonging to cellular proteins is absent, while in the red spectrum the C-H peak at 2800cm^{-1} and OH at 3200cm^{-1} in the presence of nanoparticles refers to intracellular nanoparticles. Detecting the spectra from the voxels combined with advanced data analysis therefore enables us to distinguish between extracellular and intracellular nanoparticles (Figure 4).

Figure 3 Optical images of agglomerated Co MNPs studied by Raman spectroscopy with a laser power of (A) 5mW and (B) 20mW, (C) comparison of the Raman pattern obtained from Co MNPs powder with 532nm laser excitation under low power 5mW indicated by blue spectrum (A) to higher laser power 20mW indicated by red spectrum (B).

Figure 4 Raman patterns obtained from Co MNPs outside the MCF7 cells (blue spectrum) and inside MCF7 cells (red spectrum) with 532nm laser excitation under 5mW.

Figure 5A and B exhibit two reconstructed images of MCF7 breast cancer cells incubated with Co MNPs. Figure 5A is the integrated Raman image of intensities in

the 2800–3000 cm^{-1} region, which is the lipid-protein region of cells. In Figure 5B, using k-mean cluster analysis (KCMA), we were able to distinguish between the particles (green pixels indicated by arrows). Figure 5C presents the Raman spectrum of Co MNPs, with the lipid protein peak (2800–3200 cm^{-1}), inside MCF7 breast cancer cells, while Figure 5D shows the Raman spectrum of Co MNPs outside the cells.

Figure 6 displays the 1 hour incubation of Co MNPs with different cell types: breast cancer cells MCF7 (Figure 6A and B), colorectal cancer cells HCT116 (Figure 6C and D) and dental pulp mesenchymal stem cells DPSC (Figure 6E to H). All the cells exhibit membranous cellular localization of the nanoparticles, either on the plasma membrane or on the nuclear membrane, within a span of 1 hour of nanoparticle exposure. Co MNPs seem to favour membrane anchorage when put in contact with cells, rather than cytoplasm anchorage. Noticeably in the case of HCT116 cells (Figure 6C),

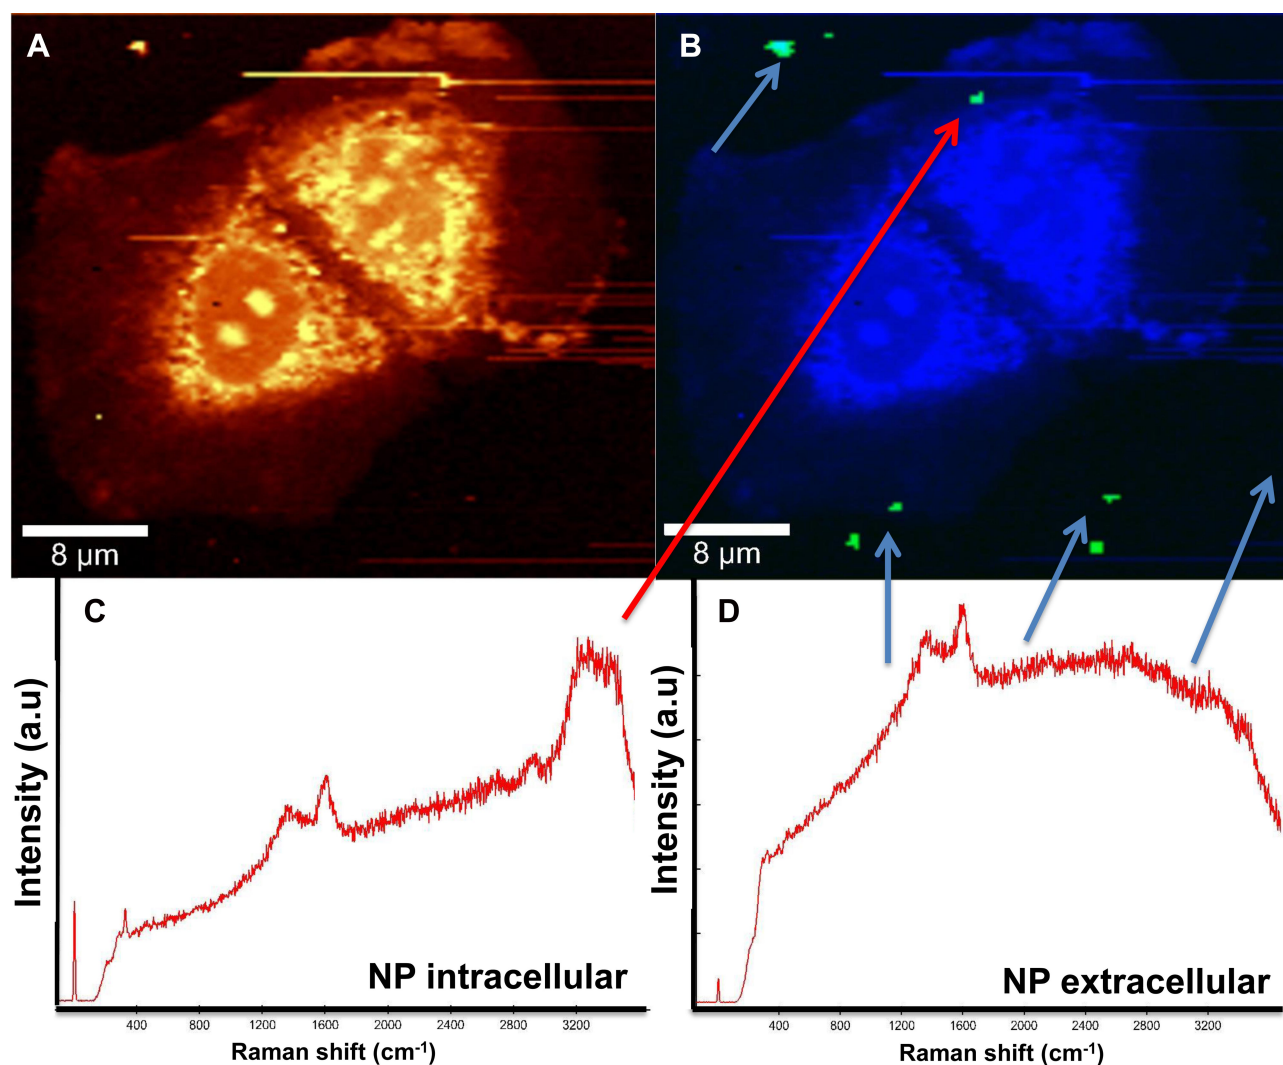

Figure 5 MCF-7 cells incubated with Co nanoparticles. **(A)** integrated Raman intensities in the 2800–3000 cm^{-1} region of cells, **(B)** Raman reconstruction of image A using KMCA to detect Co nanoparticles (green pixels indicated by arrows), **(C)** Raman spectrum of Co MNPs inside MCF7 cells (indicated by the red arrow), and **(D)** spectrum outside of the cells (blue arrows).

intracellular nanoparticles are fixed to the outer cell membrane surfaces, while subsequent internalization of nanoparticles into the cells is expected with higher incubation time (after 1 hour). This implies that a longer incubation time would be necessary for the nanoparticles to penetrate the cell nucleus.

Cytotoxicity Study

It is also important to investigate the cytotoxicity of these cobalt nanoparticles against human cells before applying them in nanomedicine. The Co element is known to be well tolerated by the human body that can easily eliminate cobalt as it is a non-accumulating metal.⁴⁶ Therefore, the cytotoxicity of PBS solutions containing Co MNPs was investigated on Human embryonic kidney HEK 293 cells.⁴⁷ Different concentrations of Co MNPs dispersed in PBS solution were

prepared and studied by MTT assay. In **Figure 7**, MTT assays were performed on Co MNP solutions of concentration ranging from 0.5 μg to 120 mg/L for 24h and the data were analysed using one way ANOVA followed by Dunnett's post hoc test. Differences were considered significant if $p < 0.05$. **Figure 7** shows the mean \pm standard error of mean (SEM) of duplicate measurements of a representative sample of three independent experiments. This toxicity study towards HEK 293 cells shows that mortality rate is very low for the studied concentrations of cobalt nanoparticles (120 mg/L (0.12ppm)) and is around 17%. For low concentrations, no visibly high toxicity was detected against HEK 293 cells. A Similar cytotoxicity study was performed on primary prostatic cancer cell line (PPC-1). **Figure 7B** presents MTT assays performed on Co

Figure 6 Raman reconstructed images showing Co MNPs inside cells (indicated by red arrows) and outside cells (indicated by blue arrows) when incubated for 1 hour with breast cancer cells MCF7 (**A** and **B**), colorectal cancer cells HCT116 (**C** and **D**) and with dental pulp mesenchymal stem cells DPSC (**E**–**H**).

MNPs solutions of concentrations ranging from 0.5µg/L to 50mg/L for 24h.

The toxicity study on PPC-1 cells indicates that the mortality rate is over 64% for a concentration of cobalt nanoparticles of 0.5µg/L and shows a higher mortality rate (over 79%) for a concentration of 50mg/L. These results therefore demonstrate that Co MNPs are potential candidates for the treatment of cancer.

Discussion

In this study, we demonstrate that Raman spectroscopy can be used as a label-free tool in order to investigate the interaction between Co MNPs and different cell types. The goal was to examine whether the Co MNPs were able to penetrate the cell membranes of cancer cells. Raman microscopy enables the efficient label-free tracing of the Co MNPs inside the cells by differentiating them from the free-standing Co MNPs outside the cells. Our study also allowed localizing the nanoparticles inside the cell by Confocal Raman data analysis.

In this study, we validate that Co MNPs easily penetrate the cell membrane of cancer cells leading to their potential apoptosis. Endocytosis is a normal process in living cells and is also known as cellular uptake. Cellular uptake of NPs involves distinctive mechanisms. In addition, cancer cells exhibit different uptake velocities and behaviours than healthy human cells.^{48,49} Endocytosis is normally used by cells for uptake of proteins and other macromolecules but also applies to NPs. It has been observed that NP uptake is usually more pronounced in cancer cells⁵⁰ and the internalization rate is also higher for more aggressive cancer cells than healthy cells,⁵¹ which can be considered as an asset for treatment options based on nanoparticle uptake. Raman spectroscopy then emerges as a convenient and rapid method towards investigating the interaction between nanomaterials and cells. This study also highlights that it is possible to induce the fast oxidation of the Co MNPs under laser irradiation of 532nm wavelength with the power of 20mW. Using phototherapy or bringing about the destruction of the cancer cells through the combustion of Co MNPs introduced within a tumour is therefore valid in such a scenario. The magnetic properties exhibited by the Co MNPs also offer the possibility to target a specific location in the body through magnetic field assistance and combine phototherapy with hyperthermia therapy. This is presently under investigation and may offer new routes towards the development of cancer theranostics in combination with hyperthermia

and phototherapy. The toxicity of the Co MNPs used in this study was also investigated in order to evaluate the validity of a potential application for cancer treatment. Furthermore, the low cytotoxicity exhibited towards HEK 293 cells indicates that the mortality rate is very low even for high Co nanoparticle concentration of 120mg/L. Conversely, the toxicity against PPC-1 cancer is very high, even at concentrations as low as 5µg/L. This establishes the high potential of cobalt metal nanoparticles for applications in nanomedicine, more particularly for cancer therapy, considering the rapid uptake of Co MNPs by cancer cells. Selectivity combined with hyperthermia capabilities of the Co MNPs make them promising candidates for the development of targeted therapies such as drug delivery. Similar results have been recently reported with Au MNPs against breast cancer cells, in which positively charged Au MNPs caused abrupt destruction of MDA-MB-231 cells.⁵² In addition, the study reports that treatment with Au NPs makes MDA-MB-231 cells sensitive to 5-fluorouracil due to epigenetic changes. In effect, DNA fragmentation was detected with Au MNPs; however, in this present study, Raman spectroscopy did not show DNA fragmentation with Co MNPs. Therefore, the Co MNPs toxicity mechanism needs to be further investigated.

In addition, we have studied the uptake of nanoparticles by mesenchymal stem cells (MSCs). New research has revealed encouraging results for the application of MSCs as cellular carriers of therapy towards cancer tissue. “Nano-engineered” MSCs have been applied in different disciplines: in delivering therapeutics to tissues, in homing to cancer or inflammatory sites and in cancer imaging and immunotherapy. This “non-genetic” engineering approach, provided by nanoparticle loading, has unique advantages in cancer therapy and is complementary to existing genetic cell manipulation.^{22,53} MSCs carrying nanoparticles (MSCs-NPs) can be used to achieve targeted anti-cancer effects. Current results indicate that MSCs-NPs combine tumour tropism and penetrative abilities of MSCs, in addition to controlled NP release.⁵⁴

Dental pulp constitutes an easily accessible and non-invasive source of mesenchymal stem cells when compared to other adult stem cell sources. Dental pulp stem cells (DPSCs) have been previously investigated for their resistance to anti-cancer drug and have revealed potential for applications in drug delivery and reduce chemotherapy side effects.^{29,32} For these reasons, we investigated the DPSCs potential uptake ability for nanoparticle delivery (Figure 6E–H). MSCs manifest high resistance to the

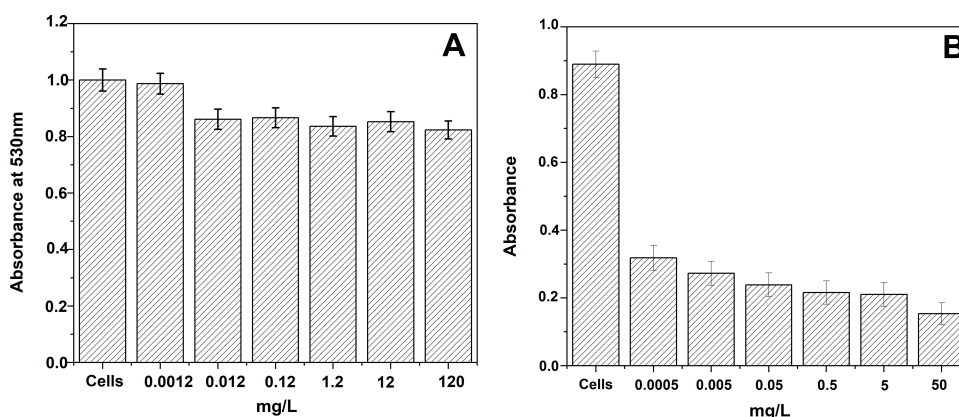

Figure 7 Toxicity test of cobalt metal nanoparticles (A) on HEK 293 cells, (B) on PPC-1 cells.

cytotoxic effect of internalized nanoparticles, as was shown with HEK 293 cell viability tests, up to high concentrations of Co MNPs (Figure 7A). On one hand, nanoparticles fixed to cell membranes have ignorable cytotoxicity to MSCs (favourable localization). On the other hand, as in the case of anticancer drug loading in cells, limited intracellular spacing makes it difficult to administer high therapeutic doses. Nanosized particles in contrast may help to maximize therapeutic loading and allow MSC migration followed by nanoparticle release into target tissues.

Conclusion

We have studied the interaction between surfactant-free cobalt metal nanoparticles with cancer cells. The investigation demonstrated the ability of non-invasive, label-free confocal Raman spectroscopy to discriminate free-standing cobalt metal nanoparticles present in a PBS solution from the nanoparticles inside the cancer cells. Raman spectroscopy enables accurate localization of the Co metal nanoparticles in a cellular environment, owing to their chemical fingerprint and advanced data analysis methods.

The facile endocytosis in cancer cells also shows that these cobalt metal nanoparticles have a potential for inducing apoptosis of cancer cells. The fact that cobalt is a non-accumulative element for the human body, contrary to iron and copper, makes Co MNPs a possible candidate for cancer treatment. Furthermore, the toxicity test performed on HEK 293 cells showed a very low toxicity of the Co MNP for concentrations lower or equal to 120mg/L. Moreover, based on the marked tropism of MSCs toward tumours, it is expected

that MSCs loaded with Co MNPs can target tumours and tumour metastases after systemic injection. The loaded Co MNPs could be released into the tumour niche through different routes: phototherapy, hyperthermia, or stem cell delivery.

The study also highlights that under a laser irradiation of 20mW with a wavelength of 532nm it is possible to locally induce combustion of the Co MNPs inside the cells, which opens new routes for cancer phototherapy. This preliminary study demonstrates the considerable capability of cobalt nanomaterials for applications in nanomedicine and further investigations are ongoing. All in all, Raman spectroscopy offers a new tool towards such implementations.

Acknowledgments

PRO-1 NANOSolutions is gratefully acknowledged for providing the cobalt metal nanoparticles used in this study. The authors thank Dr. Céline Gongora (Cancer Research Institute IRCM Montpellier, France) for providing the colorectal cancer cell line. The Center for Electron Nanoscopy at the Technical University of Denmark is acknowledged for access to their transmission electron microscopes. This research was funded by the European Regional Development Fund project EQUiTANT, grant number TK134 (F180175TIBT). This work was developed in the scope of the project CICECO-Aveiro Institute of Materials (ref. no. FCT UID/CTM/50011/2013), financed by national funds through FCT/MEC and co-financed by FEDER under the PT2020 Partnership Agreement.

International Journal of Nanomedicine

Publish your work in this journal

The International Journal of Nanomedicine is an international, peer-reviewed journal focusing on the application of nanotechnology in diagnostics, therapeutics, and drug delivery systems throughout the biomedical field. This journal is indexed on PubMed Central, MedLine, CAS, SciSearch®, Current Contents®/Clinical Medicine,

Journal Citation Reports/Science Edition, EMBase, Scopus and the Elsevier Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/international-journal-of-nanomedicine-journal>
