Purpose: Carbapenem-resistant *Enterobacterales* bloodstream infections (CRE BSIs) have a high mortality. However, an optimal antimicrobial treatment has not been determined. This study was conducted to evaluate the risk factors for mortality and provided potential therapeutic options for treatment of CRE infection.

Patients and Methods: We investigated patients with CRE BSIs from 18 hospitals across nine Chinese provinces from January to December 2019. Data were collected from the medical records according to a pre-established questionnaire. Antimicrobial susceptibility testing and DNA sequencing were performed to investigate the characteristics of isolates.

Results: A total of 208 patients enrolled; the overall 30-day mortality rate was 46.2%. The causative pathogen was carbapenem-resistant *Klebsiella pneumoniae* (CRKP) (85.6%). Patients infected by ST11-KL64 CRKP had a high sepsis/septic shock incidence rate ($p < 0.05$). Sepsis/septic shock, short duration of antimicrobial therapy and empirical using tigecycline were independent risk factors for mortality ($p < 0.05$ for each risks). Appropriate therapy had better survival benefit than inappropriate therapy ($p = 0.003$). No difference was identified between monotherapy and combination therapy ($p = 0.105$). Tigecycline as a frequently used antimicrobial had poor therapeutic effect on BSI patients ($p < 0.001$). Carbapenem-based treatment had a better therapeutic effect on patients infected by isolates with meropenem MIC ≤ 8 mg/L ($p = 0.022$). The patients who received short duration of antimicrobial therapy had poorer prognosis ($p < 0.001$) than the patients who received long duration of antimicrobial therapy.

Conclusion: Reducing the mortality of CRE BSIs need to comprehensively consider whether the antimicrobials were used appropriately, together with infection severity and CRE strains.

Keywords: carbapenem-resistant *Enterobacterales*, bloodstream infections, risk factors, antimicrobial therapy, treatment outcomes

Introduction

Carbapenem-resistant *Enterobacterales* (CRE), the Clinical Laboratory Standards Institute defined as *Enterobacterales* resistant to carbapenem or produced carbapenemases, cause severe nosocomial infections. In early 2017, the World Health

Organization listed it as a critical priority pathogen.¹ The incidence of CRE infection in China is 4.0 per 10,000 discharges.² The prevalence of CRE worldwide has always been increasing in recent years.³ The successful spread of CRE is the result of plasmid-mediated horizontal gene transfer and its clone groups.⁴ There has been an extensive increase in the use of carbapenem antibiotics since the emergence of ESBLs in *Enterobacteriales*.⁵

The therapeutic options available against CRE are limited, with only a few active antimicrobials left for use, alternative antimicrobials are usually limited to carbapenem, colistin, aminoglycosides, and tigecycline.⁶ Carbapenem is beneficial only for isolates with meropenem MIC \leq 8 mg/L.⁷ Colistin is the last choice for treatment of infections caused by multidrug-resistant Gram-negative bacteria, nephrotoxicity and heterogeneous resistance had been reported.⁸ Aminoglycosides are also active against Gram-negative organisms, a higher risk of nephrotoxicity and ototoxicity with an increase in systemic exposure.⁹ The use of tigecycline in BSIs is controversial because of its low steady-state concentrations in serum at current dosing recommendation.¹⁰ An ideal antibacterial drug means a prodrug or generally reactive compound with no specific target, broad-spectrum antibacterial activity, adequate penetration through the Gram-negative cell wall, activity in biofilms and in hard-to-treat infections, accumulation in macrophages, availability for oral administration, and for use in sensitive patient groups.¹¹ Antimicrobials recently approved are summarized in Gajdács M's article.¹²

BSIs caused by CRE were associated with poor prognosis. The all-cause mortality from severe CRE BSIs was nearly 70%, and CRKP BSI patient mortality rate was three times higher than those of other infections.¹³ The best available treatment against CRE BSIs is unknown. So, this study was conducted to comprehensively evaluate risk factors for mortality and provided the potential therapeutic options for the treatment of BSIs due to CRE.

Patients and Methods

Study Design and Patient Selection

This study prospectively investigated patients with CRE BSIs from 18 hospitals across nine Chinese provinces from January to December 2019. The patients (\geq 18 years old) with CRE BSIs (BSI was defined as at least one positive blood culture for a recognized pathogen and clinical symptoms consistent with bacteremia) were included and followed-up until discharge or death. The exclusion

criteria included children and missing key data. Polymicrobial bacteremia was also excluded. Each patient was included only once.

Clinical and Epidemiological Data

Data were collected from the medical records according to a pre-established questionnaire. The following information was recorded: demographics (age and sex); clinical characteristics; ward; comorbidities; invasive procedures (arterial cannula, central venous catheter, tracheal cannula, tracheotomy, urinary catheter, and gastric tube); laboratory findings; empirical antimicrobial use in the 30 days prior to infection; Acute Physiology and Chronic Health Evaluation (APACHE) II score and Pitt bacteremia score at bloodstream infection onset; severity of underlying illness (measured using the Charlson comorbidity index score) at the time of admission; development of sepsis/septic shock, and antimicrobial treatment and outcome. The primary outcome was all-cause 30-day mortality, and the secondary outcomes included the 14-day mortality, clinical cure, and sepsis/septic shock incidence rate.

Definitions

Empirical therapy was defined as the antimicrobials administered before a susceptibility report was available. Appropriate empirical therapy was defined as that in vitro active antimicrobials were administered against the isolates within 24 h of infection onset and at least 48 h.¹⁴ Definitive therapy referred to antimicrobial therapy after the susceptibility testing results were available, defined as appropriate therapy if at least one in vitro active antimicrobial was administered within 5 days of infection and for at least 48 h, or as inappropriate therapy if these criteria were not met. Early appropriate therapy was considered the administration of an in vitro active antimicrobial within 48 h of infection onset. Combination therapy was defined as the administration of more than one in vitro active antimicrobial treatments, and monotherapy was defined as the administration of only one active antimicrobial treatment.¹⁵ The antimicrobials were chosen by the clinical physicians. Based on previously published studies, carbapenems were considered active if MIC \leq 8 mg/L,¹⁶ tigecycline was considered active if MIC \leq 4 mg/L, and colistin was considered active if MIC \leq 2 mg/L. Treatment was considered a clinical cure if the patients survived, the clinical symptoms associated with bacteremia disappeared, microbiological clearance occurred, and the relevant laboratory parameters improved. If the therapy was

changed, we considered the antimicrobial treatment as the one that started within 5 days after BSI onset and at least half of the therapy duration. Sepsis/septic shock was defined according to international definitions.¹⁷ Short-duration treatment was defined as receiving antimicrobial treatment <10 (4–9) days and long-duration treatment was defined as receiving antimicrobial treatment ≥10 days.

Bacterial Microbiology and Resistance Gene Identification

All participating hospitals sent CRE isolates to Peking University People's Hospital for isolates reappraisal and antimicrobial susceptibility testing. CRE was identified using matrix-assisted laser desorption ionisation–time of flight mass spectrometry (IBM Corp., Armonk, NY, USA). MICs were determined by broth microdilution or agar dilution according to guidelines (2020) described in CLSI M100 S30 (<http://www.clsi.org>). The tigecycline and colistin breakpoints were defined according to guidelines of the US Food and Drug Administration and European Committee on Antibiotic Susceptibility Testing, respectively. A total of 194 isolates were obtained from the whole gene sequence (Novogene, in Beijing, China) using Illumina technology. Resistance genes and Virulence genes were determined according to the Center for Genomic Epidemiology (CGE) website (<http://www.genomicepidemiology.org>). Multilocus sequence typing (MLST) was confirmed according to the Pasteur Institute MLST website (<http://bigsdbs.pasteur.fr/klebsiella/klebsiella.html>) for *K. pneumoniae* and the MLST websites for *E. coli* (<http://mlst.warwick.ac.uk/mlst/dbs/Ecoli>), *E. cloacae* (<https://pubmlst.org/ecloacae/>). Capsule genotyping was identified using Kleborate (<https://github.com/katholt/Kleborate>).

Statistical Analyses

Data were analyzed using SPSS (version 26) (SPSS Inc., Chicago, IL, USA). Categorical data were compared using the Pearson's χ^2 test or Fisher's exact test, continuous variables with the Mann–Whitney *U* or Student's *t*-test. The risk factors were analyzed using univariable logistic regression, and age, sex, and the univariable with $p < 0.05$ were included in the multivariate logistic regression models. Survival on 14/30 days was plotted as Kaplan–Meier curves and compared using the Log rank test. $P < 0.05$ was considered statistically significant. Propensity score matching was analyzed using R (version 4.02). The graph was created using GraphPad Prism (version 8).

Ethics Approval

This study protocol was approved by the medical ethics committee of Peking University People's Hospital (approval number: 2018PHB248-01) and a waiver of patient consent exemption was granted, because this study was observational and the patient information were kept confidential, the clinical samples were part of the routine hospital laboratory procedure. This study was in accordance with the declaration of Helsinki.

Results

Study Population

During the study period, 221 patients with BSIs caused by CRE were observed.

According to the inclusion and exclusion criteria, 208 patients were ultimately enrolled in this study. A flow chart of the study is shown in Figure 1. A total of 69.7% (145/208) of the patients were males. The median age was 57 (interquartile range: 44.0–69.0) years. Among the patients, 87.5% (182/208) of the episodes were nosocomial infections. Also, 62.5% (130/208) of the patients were hospitalized in ICU at the onset of BSI, whereas 22.1% (46/208) in medical wards (among them, 50% patients were hospitalized in hematology), 13.9% (29/208) in surgical wards, and 1.5% (3/208) in emergency department.

The Risk Factors of Mortality

Univariate analyses comparing the baseline characteristics of patients who survived or died are shown in Table 1. The all cause 30-day mortality was 46.2% (96/208). The univariate analysis results indicated the variables associated with mortality as follows: Charlson comorbidity index ($p = 0.002$), tigecycline MIC ≥ 0.5 mg/L ($p = 0.009$), ICU admission at time of BSI onset ($p = 0.044$), arterial cannula ($p = 0.023$), central venous catheter ($p = 0.011$), urinary catheter ($p = 0.030$), use of antimicrobial in the prior 30 days ($p = 0.035$), empirical treatment using tigecycline ($p = 0.030$), Pitt bacteremia score ($p = 0.001$), sepsis/septic shock ($p < 0.001$), and the short-duration of antimicrobial therapy ($p < 0.001$). Patients who died as a result of infection had shorter hospital stays ($p < 0.001$) than the survived patients.

Multivariate analysis indicated that sepsis/septic shock (OR 4.863, 95% CI 1.815–13.033, $p = 0.002$), the empirical use of tigecycline (OR 4.664, 95% CI 1.604–13.562,

Figure 1 Flow chart of included patients with BSIs infected by CRE.

$p = 0.005$) and short-duration of antimicrobial therapy (OR 8.625, 95% CI 3.008–24.732, $p < 0.001$) were independent risk factors of mortality (Table 2).

The Risk Factors of Sepsis/Septic Shock

The baseline characteristics of patients with sepsis/septic shock are shown in Table 3. In patients with sepsis/septic shock, arterial cannula ($p = 0.019$), gastric tube ($p = 0.012$), history of critical care in prior 1 year ($p = 0.027$), and Pitt bacteremia score ($p = 0.009$) were found frequent and high. Furthermore, more patients with sepsis were infected by ST11-K64 CRKP ($p = 0.008$). A small number of patients with sepsis were exposed to third- or fourth-generation cephalosporins in the previous 30 days of admission ($p = 0.014$).

Multivariate analysis indicated that ST11-K64 CRKP (OR 3.365, 95% CI 1.564–7.237, $p = 0.002$), gastric tube (OR 2.064, 95% CI 1.238–5.477, $p = 0.012$) and history of critical care in prior 1 year (OR 2.218, 95% CI 1.061–4.637, $p < 0.001$) were independent risk factors of sepsis/septic shock (Table 4). Patients who developed sepsis had a higher 30-day mortality than the non-sepsis patients (Supplemental Figure S1).

Antimicrobial Susceptibility Results and Microbiological Features

Of the 208 CRE isolates, *K. pneumoniae* was found to be the predominant clinical species (85.6%, 178/208), followed by *E. coli* (9.1%, 19/208), *E. cloacae* (4.3%, 9/

208), and *K. oxytoca* (1.0%, 2/208). 190 CRE isolates were tested antimicrobial susceptibility testing, 194 CRE isolates were performed whole gene sequence. The results of antimicrobial susceptibility testing are shown in supplemental Table S1. The antimicrobial susceptibility rates were as follows: colistin, 93.2%; tigecycline, 92.1%; amikacin, 34.7%; minocycline, 34.2%; aztreonam, 6.8%; levofloxacin, 4.7%; ciprofloxacin, 3.7%; meropenem, 2.1%; imipenem, 3.2%; ertapenem, 0.5%. The 30-day mortality was statistically higher among patients infected by isolates with tigecycline MIC ≥ 0.5 mg/L than those with tigecycline MIC < 0.5 mg/L (Figure 2A). Different resistance levels associated with 30-day mortality were not found between meropenem and colistin.

The majority of CRE isolates expressed *bla*_{KPC-2} (75.3%, 146/194), followed by *bla*_{NDM} (17.5%, 34/194). The most dominant sequence type was ST11 (69.6%, 135/194). Among the 194 sequenced CRE isolates, 167 isolates were *K. pneumoniae*. The most common capsule genotype in *K. pneumoniae* was KL64 (43.7%, 73/167), followed by KL47 (30.5%, 51/167). Patients infected with ST11-KL64 CRKP had a significantly higher sepsis/septic shock incidence rate than those infected with ST11-KL47 CRKP (52/73 vs 27/51, $p = 0.050$) or another K_locus CRKP (41/73 vs 21/43, $p = 0.016$) (Figure 2B).

Treatment Outcome

The details of the definitive antimicrobial regimes are shown in Table 5. Of the 208 CRE BSI patients, 135

Short-duration	4.802 (2.355–9.792)	<0.001	8.625 (3.008–24.732)	<0.001

Note: *P < 0.05 (bold values) was considered statistically significant.

received appropriate therapy, 73 received inappropriate therapy. Kaplan–Meier analysis showed that the patients who received the appropriate therapy had a 14-day survival benefit compared to patients who received inappropriate therapy ($p = 0.003$) (Figure 3A). Among the 135 patients who received appropriate therapy, 92 received monotherapy, 43 received combination therapy, no difference was observed in 14-day mortality between monotherapy and combination therapy ($p = 0.105$) (Figure 3B). Among the 135 patients who received the appropriate therapy, 112 patients received in vitro active tigecycline treatment. The patients who received active tigecycline treatment had poorer therapeutic outcomes than patients who did not receive active tigecycline treatment ($p < 0.001$) (Figure 3C). There was no difference in 30-day mortality between tigecycline monotherapy and tigecycline-based combination therapy ($p = 0.530$). Twenty-two patients who received active carbapenem-based treatment had survival benefit compared to patients who did not receive active carbapenem-based treatment ($p = 0.022$) (Figure 3D).

The propensity score matching was undertaken to control the confounding factors of baseline characteristics of patients who received short or long duration of antimicrobial therapy (Supplemental Table S2). Kaplan–Meier analysis showed that the patients who received short-duration of antimicrobial therapy had poorer prognosis than the patients who received long-duration of antimicrobial therapy (Figure 4).

Discussion

CRE BSIs are associated with high mortality in patients. However, an optimal antimicrobial treatment for these infections has yet to be determined. Furthermore, the data provided therapeutic recommendations from prospective studies

are lacking. In the present study, a prospective multicenter observational investigation was used to evaluate risk factors for mortality and provided the potential therapeutic options for the treatment of BSIs due to CRE. The overall 30-day mortality of patients with CRE BSIs was 46.2%, which is higher than that previously reported in China (approximately 32.9%).¹⁸ The mortality was higher than *Pseudomonas aeruginosa* bacteremia in China.¹⁹

Many factors could affect the prognosis of patients, including individual risk factors, severity of illness, pathogen characteristics, and antimicrobial therapeutic effect. The severity of underlying diseases, as well as the presence of septic shock, are important in patient's prognosis.¹⁶ In this study, sepsis/septic shock was found to develop in 59.6% of the patients, and the 30-day mortality rate of sepsis/septic shock was calculated as 60.5%. Furthermore, sepsis/septic shock was found to be an independent risk factor for mortality, patients with sepsis or septic shock had a high risk of mortality after discharge.²⁰ Life support interventions, such as arterial cannula, central venous catheter, and urinary catheter, in critical patients can lead to the damage of mucosa, and then increase the incidence of BSIs since the majority of the bacteria are able to pass through the mucosal barrier into the blood flow. Another reason for the increased mortality is due to patients refusing the necessary invasive interventions for economic reasons or traditional beliefs, which can lead to delays in treatment and even death.²¹

Pathogen-associated factors, such as organisms, antimicrobial MIC levels, resistance genes, virulence genes, and capsule genotype, can also affect the patient's treatment outcome and prognosis. A previous study found that the patients infected by isolates with meropenem MIC >8 mg/L had a higher 30-day mortality.²² Another study showed that isolates producing metallo- β -lactamase have better survival benefits than those producing KPC-2 or

others did not produce carbapenemase.¹⁸ In our study, the leading causative pathogen was ST11-KPC-2 CRKP. Patients infected with ST11-KL64 CRKP had a significantly higher sepsis/septic shock incidence than patients infected with ST11-KL47 CRKP or other capsule genotypes. One study found that ST11-KL47, a dominant clone sequence type, was replaced by ST11-KL64. The latter had a remarkably higher 30-day mortality in patients than other CRKP infected patients in China.²³ These results are in agreement with our own research findings. Patients infected by pathogens with tigecycline MIC \geq 0.5 mg/L had a significantly higher 30-day mortality than those with tigecycline MIC < 0.5 mg/L. Colistin and meropenem MIC resistance levels were not associated with 30-day mortality.

Different antimicrobial treatments have different prognoses, and the optimal antimicrobial treatment for CRE BSIs has not been determined. In our study, patients treated with an appropriate therapy had a better prognosis than those treated with an inappropriate therapy. These results were similar to those reported in other studies.¹³ Combination therapy with two or more active antimicrobials is widely accepted in vitro experiment.²⁴ Some studies have found that combination antimicrobial therapy is preferred to monotherapy, particularly in severely ill

patients.²⁵ In the present study, no difference was observed in the 30-day mortality between patients treated with monotherapy and combination therapy.

Appropriate empirical therapy is key for decreasing the mortality associated with sepsis and septic shock. Some studies have found the benefits of empirical combination therapy, which broadens the antibacterial spectrum.²⁵ However, initial inappropriate empirical has been found to increase hospital mortality.²⁶ In our study, no significant advantage was observed between patients who received early appropriate therapy or appropriate empirical therapy. The empirical use of tigecycline was associated with mortality. This phenomenon can be explained by the fact that previous antimicrobial exposures could increase the risk of antimicrobial-resistant bacterial colonization or infection, and thus have an effect on mortality. Therefore, decisions about empirical therapy need to be cautious.

Tigecycline is an alternative antimicrobial to counteract the challenges associated with the treatment of infections caused by CRE. However, clinicians should be careful when using tigecycline because it is associated with a higher mortality than other similar antimicrobials.²⁷ In meta-analyses of randomized trials, tigecycline was found to increase the risk of mortality and clinical failure.²⁸ In our study, tigecycline was found to have a poorer therapeutic

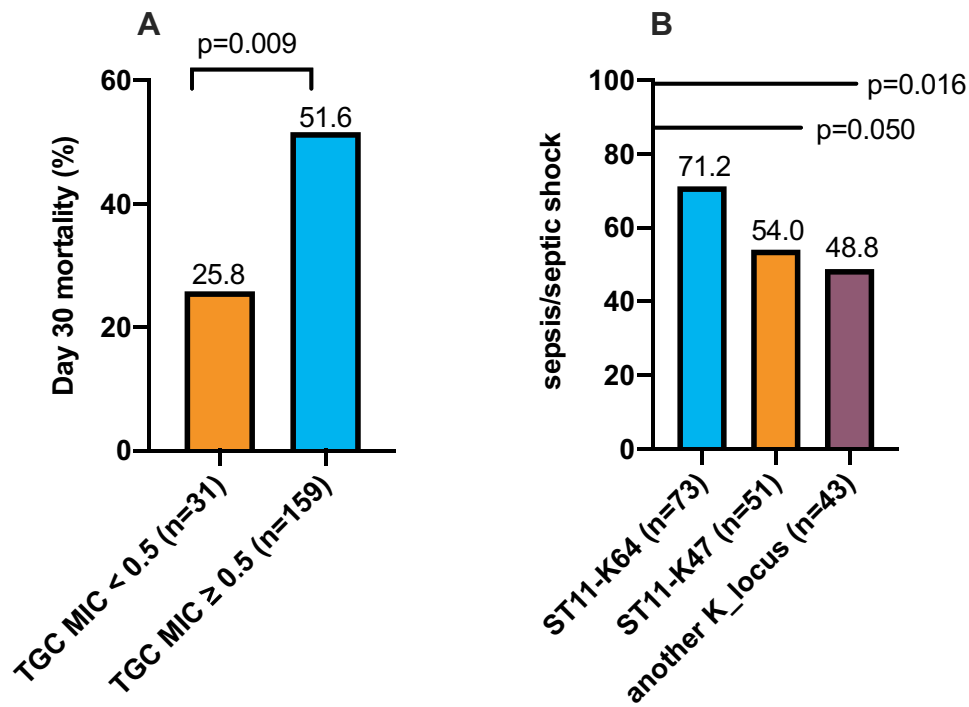

Figure 2 Microbiological characteristics of CRE isolates associated with the prognosis of patients. (A) The 30-day mortality was statistically higher among patients infected by isolates with tigecycline MIC ≥ 0.5 mg/L than those with tigecycline MIC < 0.5 m g/L; (B) patients infected with ST11-KL64 CRKP had a significantly higher sepsis/septic shock incidence rate than those infected with ST11-KL47 or another K_locus.

Table 5 Detailed Antimicrobial Therapy of Patients with BSIs Caused by CRE

Antimicrobial Regimens*	n (%)	30-Day Mortality, n (%)
Inappropriate therapy	73 (35.1)	39/73 (53.4)
Appropriate therapy	135 (64.9)	57/135 (42.2)
Monotherapy*	92 (68.1)	36/92 (39.1)
Tigecycline	71 (77.2)	32/71 (45.1)
Carbapenem	10 (10.9)	1/10 (10.0)
Amikacin	6 (6.5)	1/6 (16.7)
Polymyxin B sulfate	3 (3.3)	1/3 (33.3)
Ceftazidime/avibactam	1 (1.1)	0/1 (0)
Combination therapy#	43 (31.9)	21/43 (48.8)
Tigecycline + polymyxin B sulfate	21 (48.8)	15/21 (71.4)
Tigecycline + carbapenem	6 (14.0)	2/6 (33.3)
Tigecycline + amikacin	6 (14.0)	2/6 (33.3)
Ceftazidime/avibactam + imipenem	1 (2.3)	0/1 (0)
Tigecycline + polymyxin B sulfate + imipenem	2 (4.7)	0/2 (0)
Tigecycline + polymyxin B sulfate + amikacin	2 (4.7)	1/2 (50.0)
Tigecycline + carbapenem + amikacin	2 (4.7)	1/2 (50.0)
Tigecycline + ceftazidime/avibactam	2 (4.7)	0/2(0)
Imipenem + amikacin	1 (2.3)	0/1(0)

Notes: *During the study period, the usual antimicrobial dosages were the following: for polymyxin B sulfate, a loading dose of 2.5mg/kg followed by 1.5mg/kg every 12h; for tigecycline, a loading dose of 100mg followed by 50mg every 12h; for carbapenem, a dosage of 1 or 2 or 0.5g every 8h; for amikacin, a dosage of 0.4g every day or 0.2g every 12h; for ceftazidime/avibactam, a dosage of 2.5g every 8h. *Monotherapy was defined as only one active antimicrobial treatment. #Combination therapy was defined as the administration of more than one in vitro active antimicrobial treatments.

Figure 3 Kaplan–Meier curves showing the impact of different antimicrobial treatment. **(A)** The appropriate therapy had a 14-day survival benefit compared to patients who received inappropriate therapy; **(B)** no difference was observed in 14-day mortality between the monotherapy or combination therapy groups; **(C)** the patients who received active tigecycline treatment had poorer therapeutic outcomes than patients who did not receive active tigecycline treatment; **(D)** the patients received active carbapenem-based treatment had survival benefit compared to patients who did not receive active carbapenem-based treatment.

effect than patients received without active tigecycline treatment. No significant difference was observed between tigecycline monotherapy and combination therapy. Probable reasons for this result may be its bacteriostatic activity and its low steady-state concentration in serum at standard dosing recommendations. It is worth noting that high doses of tigecycline have been reported to be associated with a better outcome without significant adverse effects.²⁹

In the present study, patients infected by pathogens with meropenem MIC ≤ 8 mg/L using active carbapenem-based treatment were found to have a better therapeutic outcome than patients treated without using carbapenem treatment.

Figure 4 Kaplan–Meier analysis showed that the patients who received short-duration (<10 days) of antimicrobial therapy had a poorer prognosis than the patients who received long-duration (≥ 10 days) of antimicrobial therapy.

However, the vast majority of KPC-producing CRE were highly resistant to carbapenem (MIC > 8 mg/L). Therefore, future studies should take a closer look at potential alternative drugs. For example, new pump inhibitor drugs or molecules of natural origin could also be used as a new frontier in antimicrobial therapy.^{30–32}

Colistin is increasingly being used as a last resort for infections caused by CRE. The resistance rate of this drug is rising, and its potential for toxicity (both nephrotoxicity and neurotoxicity) limited its clinical use. Clinical observations suggest mortality was significantly higher with polymyxin monotherapy compared with combination therapy with tigecycline, aminoglycosides or fosfomycin for *K. pneumoniae* bacteraemia that is very low quality evidence.³³ In our study, the polymyxin B sulfate–tigecycline combination therapy was associated with high mortality, possibly due to most of the polymyxin B sulfate being used as “salvage treatment” and the patients were seriously ill. More randomized controlled trials need to explore its effect.

The recommended duration of antimicrobial treatment for *Enterobacteriales* BSIs is 7–14 days.³⁴ One meta-analysis found that the short-duration of antimicrobial therapy was as effective as long-duration of antimicrobial therapy for many common infections.³⁵ In our propensity score-matched cohort

study, we found that the short-duration of antimicrobial therapy resulted in a poorer prognosis than long-duration of antimicrobial therapy in patients with BSIs caused by CRE. The inconsistent results can be attributed to differences in the infection strains (more virulence) and the sources of bacteremia or the heterogeneity of patient severity. This requires large numbers of research to support this conclusion.

This study has several limitations that should be taken into consideration. Firstly, as an observational study, any unmeasured variables or residual confounding effects cannot be discarded. Secondly, information on the timing of the source control was not collected, the control of infectious sources was associated with well-defined outcomes. Lastly, the number of samples included was not large. Large sample data and randomized controlled studies are needed to study the clinical characteristics and different antimicrobial therapeutic effects on patients with CRE BSIs.

Conclusion

In conclusion, the study analyzed the risk factors of mortality, the commonly used antimicrobial therapy and treatment outcomes, provided the latest information that may assist physicians to adopt more effective approaches for the treatment of CRE BSIs.

Acknowledgments

This work was supported by the Capital's Funds for Health Improvement and Research (grant number. 2018-1-4081). The author would like to thank all the patients for their participation in this study. For providing CRE isolates and reviewing medical records, we thank Yi Li, Junping Liu at Department of Clinical microbiology, Henan Province people's Hospital; Yi Xie at Department of Clinical microbiology, West China Hospital, Sichuan university; Lei Huang at Department of Clinical microbiology, Peking University First Hospital; Jingxian Yang at Department of Clinical microbiology, Aerospace Center Hospital; Haiquan Kang at Department of Clinical Laboratory, The Affiliated Hospital of Xuzhou Medical University; Jinwei Huang at Department of Clinical Laboratory, Fifth Affiliated Hospital of Wenzhou Medical University; Ju Cao at Department of Clinical Laboratory, Chong Qing Medical University; Tianxin Xiang at Department of Clinical Laboratory, The First Affiliated Hospital of Nanchang University; Jinping Xiao at Department of Clinical Laboratory, The first affiliated hospital of Jiangxi medical college; Han Meng, Jinghong Feng at Department of Clinical microbiology, Peking University People's Hospital; Chunlei Wang, Xiaoxuan Feng

Infection and Drug Resistance

Publish your work in this journal

Infection and Drug Resistance is an international, peer-reviewed open-access journal that focuses on the optimal treatment of infection (bacterial, fungal and viral) and the development and institution of preventive strategies to minimize the development and spread of resistance. The journal is specifically concerned with the epidemiology of

antibiotic resistance and the mechanisms of resistance development and diffusion in both hospitals and the community. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
