Background: Successful cardiopulmonary resuscitation after drowning or avalanche is often attributed to hypothermia-induced decrease in metabolism, which adapts the oxygen demand to the amount supplied under cardiac compression. Four decades ago, we speculated if oxygen-sparing mechanisms like those found in marine mammals, may improve cerebral oxygenation during acute airway blockade in humans. We investigated hemodynamic changes during steady state ergometer cycling with intermittent periods of apnea and face immersion (AFI) in ice-cold water. During AFI, heart rate (HR) dropped by 58% whereas average blood velocity (ABV) determined by means of a Doppler ultrasound velocity meter (UNIDOP University of Oslo, Oslo, Norway) fell by 85% in the radial artery and rose by 67% in the vertebral artery. Similar changes occurred in radial artery ABV, albeit more slowly, when the test subject only held his breath while cycling. When he breathed via a snorkel during face immersion, HR remained unchanged while radial artery ABV fell transiently and subsequently returned to its pre-immersion level. These findings later were confirmed by other investigators. Moreover, a recent study revealed that the seal even has a system for selective brain cooling during the dive.

Conclusion: Our research has confirmed prioritized cerebral circulation during AFI in cold water. We hypothesize that these changes may improve brain oxygenation due both to greater blood flow and possibly also to faster brain cooling, as demonstrated in diving seals.

Keywords: apnea, breath-hold, cardiopulmonary resuscitation, diving response, hypothermia

Introduction

Throughout more than half a century, physicians have reported successful cardiopulmonary resuscitations after lengthy periods of asphyxia and cardiac arrest following drowning and avalanche.^{1,2} Most authors ascribe their success to hypothermia-induced decrease in metabolism, which adjusts oxygen consumption to the supply being delivered during cardiac compression. According to Fodden et al, trained personnel using standard cardiopulmonary resuscitation techniques were able to obtain cardiac output (CO) values consistent with those observed during rest in human.³

In 1980, we speculated whether oxygen-saving mechanisms of marine mammals, that had been demonstrated in noninvasive experiments on humans, possibly could contribute to prevent anoxic brain injury under conditions of inhibited breathing in man.^{4,5} In a heart catheterization study, while exercising at constant

workload on an ergometer cycle, two male subjects underwent periods of apnea and face immersion (AFI) as long as they could endure (30–45 seconds) in a basin filled with ice-cold water.

During AFI, heart rate (HR) fell from maximums obtained during steady state cycling of 160 and 150 beats/min, to nadirs of 40 and 50 beats/min, respectively. Concomitantly, CO fell by approximately 50% from 24 and 18 L/min, respectively. Despite a rise in systemic vascular resistance by nearly 200%, myocardial oxygen demand, determined as the HR pressure product, decreased by 42%.⁶ These findings inspired us to perform a hypothesis-forming experiment during ergometer cycling with periods of AFI at which we compared blood flow patterns in a radial artery and a vertebral artery, as representatives of a peripheral artery and an artery supplying the brain. Due to reasons explained below, publication of this pilot experiment was postponed until now.

Case Presentation

When we carried out the heart catheterization study and the present pilot experiment in 1980, research ethical committees did not exist in our country and ethical approval was not required.^{6,7} A 39 years old male with good knowledge of the study protocol, consented to act as test person. We used the same ergometer bicycle set-up as employed in the heart catheterization study. A pulsed Doppler ultrasound velocity meter (UNIDOP, University of Oslo, Oslo Norway), was used to determine average blood velocity (ABV) in meter per second (m/s) in a radial artery and a vertebral artery, respectively, as described previously.⁸ When the test person cycled at the same constant workload (163 Watt) as in our previous study, we determined ABV in the right radial artery by means of a 6 MHz hand-held pulsed Doppler ultrasound transducer, and correspondingly, with a 1.5 MHz transducer in the vertebral artery.^{6,8,9} The transducers were positioned in right angle towards the respective arteries; first while the test subject breathed freely and subsequently while he held his breath and immersed his face into a basin filled with ice cubes in water (AFI). We registered HR from the electrocardiogram (ECG) signals with electrodes placed on the shoulders and the left iliac crest. The test person rested his right forearm on an arm board while one of the investigators searched up the optimal Doppler-ultrasound signals from the radial artery. Without moving his forearm, the test person carefully bent his upper body and started AFI, which lasted as long as he could endure (30–45

seconds), until he carefully withdrew his face and resumed breathing. The ABV measurements were repeated while the test person cycled with the same workload and held his breath without immersing his face, and finally, while breathing via a snorkel during the face immersion.

When assessing the right vertebral artery ABV, the examiner positioned the Doppler ultrasound transducer as described previously.⁹ While the test person cycled at the same constant workload as in the afore mentioned study, velocity meter signals were obtained both before he carefully bent his upper body forward for AFI, during AFI, and shortly after he cautiously withdrew his face from water.⁶

During ergometer cycling with constant workload, the radial artery ABV presented with respiration-synchronous changes, as shown during the first half a minute in [Figure 1A](#). When steady state was obtained, as judged by HR of 150–160 beats/min, the test person began AFI (arrows indicate start and end), whereupon radial artery ABV signaling fell by 85%, in parallel with a 58% decline in HR ([Figure 1B](#)), as compared with the preceding period when he breathed freely. Subsequently, the test person held his breath without face immersion while cycling at the same workload. This resulted in similar patterns of decreased ABV ([Figure 2A](#)) and HR ([Figure 2B](#)), although developing at a slower pace. Of note, we observed sudden bursts in HR during the bradycardia periods both in [Figures 1B and 2B](#). We also wondered if exposure to ice-cold water alone would trigger the decreases in radial artery ABV and HR. During exposure to the same workload, the test person underwent a new period of cold water face immersion while breathing through a snorkel. However, this time radial artery ABV fell only transiently and returned to the preceding level before he had withdrawn his face from water ([Figure 3A](#)). We observed no concomitant drop in HR ([Figure 3B](#)). Finally, we investigated right vertebral artery ABV at the same workload as used above ([Figure 4](#)). During the ergometer cycling, ABV increased from 0.24 m/s to 0.40 m/s (67%) during AFI, and subsequently returned to 0.20 m/s after AFI. Thus, even during strenuous muscular exercise, AFI appears to redistribute blood flow from the periphery to the brain circulation.

Discussion

When the test person cycled at constant workload, radial artery ABV dropped by 85% and vertebral artery ABV increased by 67% during AFI in ice-cold water.

Figure 1 Average blood velocity in right radial artery (**A**) and heart rate (**B**) vs time of a test person during steady state ergometer cycling. Arrows indicate start and stop of a period of apnea and facial immersion (AFI) in ice-cold water.

Concomitantly, HR fell by almost 60%. The fall in radial artery ABV is consistent with reduced forearm blood flow, as determined by venous occlusion plethysmography during breath hold and whole body immersion at rest.⁵ When the test person performed breath holding without immersing face in cold water, both radial artery ABV and HR fell more slowly. Moreover, when he breathed through a snorkel during face immersion in cold water while maintaining unaltered workload, his radial artery ABV dropped only transiently with no concomitant fall in HR. This indicates that despite cycling at a relatively high muscular workload, the “cold shock response” potentiates redistribution of arterial blood from the periphery to the brain, as recently reviewed by Shattock and Tipton.¹⁰

We cannot argue that the AFI-associated redistribution of blood flow was entirely due to the so-called

diving response. In the heart catheterization study, we measured end-expiratory (Alveolar, A) partial pressures of carbon dioxide ($P_A\text{CO}_2$) and oxygen ($P_A\text{O}_2$), by mass spectrometry following AFI (as median and range) to 10.0 (9.1–10.2) kPa and 5.6 (5.4–5.7) kPa, respectively, when exercising at the same workload.⁶ Since $P_A\text{CO}_2$ increased by nearly 100% at the end of AFI, the increase in vertebral artery ABV might have resulted, from increased $P_A\text{CO}_2$, as reported by Hauge et al some years ago.⁹ In addition to the effect on vertebral artery ABV of almost a doubling of $P_A\text{CO}_2$ as compared to normal, the concomitant effect of a more than 50% decrease in $P_A\text{O}_2$ also might have contributed to the increase in vertebral artery ABV, since a decrease in $P_A\text{O}_2$ below 6.7 kPa has been suggested to cause cerebral vasodilation.^{11,12}

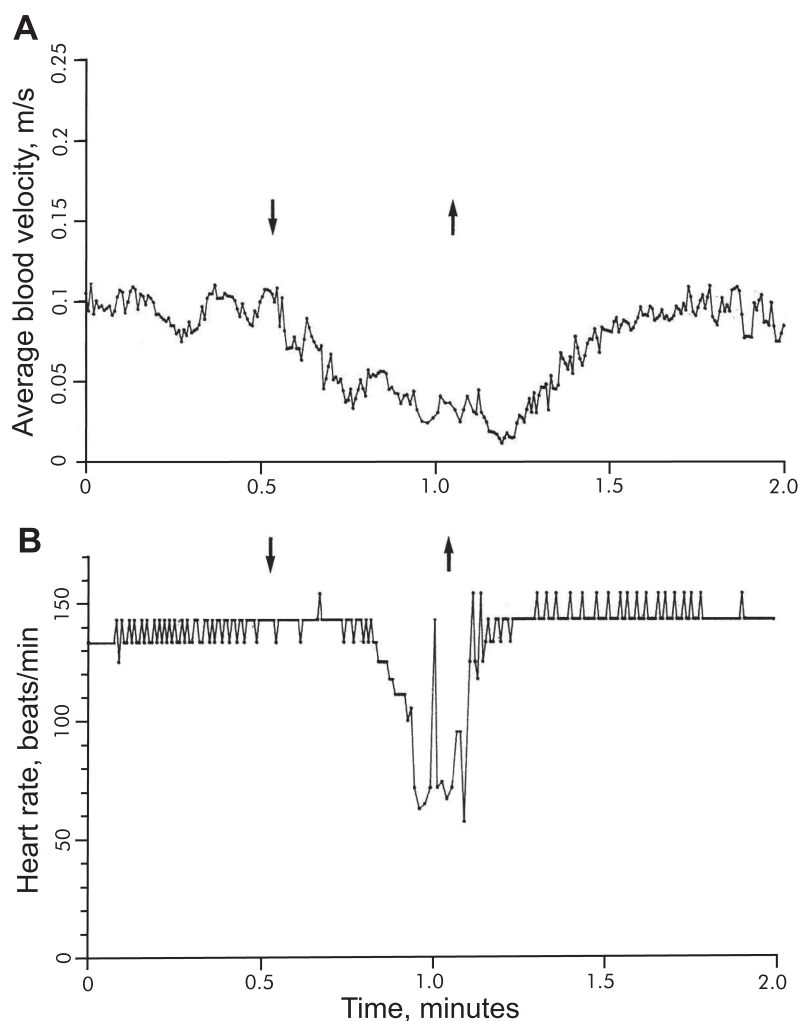

Figure 2 Average blood velocity in right radial artery (**A**) and heart rate (**B**) vs time of a test person during steady state ergometer cycling. Arrows indicate start and stop of an apnea period without face immersion in ice-cold water.

We found no study similar to the present one until 2009 when Kjeld et al reported nearly a 180% increased ABV in the middle cerebral artery (MCA) during periods of apnea at rest. Concomitantly, arterial PCO_2 (PaCO_2) increased from 4.2 to 6.7 kPa. While the investigators cycled at a workload of 100 Watt, ABV in MCA increased by 105% during breath holding, and by a further 9% during AFI in water of 10 °C.¹³ This finding is consistent with the present observation of increased ABV in the vertebral artery during AFI in ice-cold water while the test person cycled at a slightly higher workload.

It is an interesting thought that the central blood redistribution, as demonstrated here, might lead both to increased cerebral oxygen supply, and possibly also contribute to more rapid cooling of the brain in conditions with impeded respiration. In victims of drowning or burial by

avalanche, redirecting oxygenated blood to the brain, which is the most sensitive organ to lack of oxygen, probably increases the chance of surviving. Moreover, a faster brain cooling, as demonstrated during experimental dives in seals, might reduce local metabolism, thereby making the oxygen supplied during the cardiac compression to last longer and protect the brain more efficiently against anoxic injury.¹⁴ Although we consider the duration of AFI as being too short for a brain cooling effect during this experiment, the mechanism might have played a role for the outcome of a 40 year old man, who fell into a ditch without being able to rescue himself. He suffered cardiac arrest when the paramedics lifted him into the ambulance and was subjected to cardiac compression for 4 ½ hrs during transfer (by ambulance helicopter) to a tertiary hospital where he was successfully resuscitated with cardiopulmonary bypass

(CPB) from a body core temperature of 25 °C. He was weaned off CPB nearly seven hrs after CA and recovered without sequela.¹⁵

Our findings have limitations aside from the fact that we performed the experiments only on one person more than 40 years ago. Initially, we interpreted the outbreaks of increased HR during AFI (Figures 1B and 2B) as technical errors. However, when the test person was examined for paroxysmic atrial fibrillation (year 2002), he presented with episodes of ectopic ventricular beats on the electrocardiogram (ECG) during ergometer bicycling. In 2012, Shattock and Tipton introduced the concept “autonomic conflict”, which is a potential mechanism of arrhythmia and a frequent cause of unexpected deaths in cold water. A variety of arrhythmias have been reported, such as atrioventricular blocks, atrial fibrillation, ectopic

ventricular beats and prolonged QT times. Therefore, in retrospect, we have reason to believe that ectopic ventricular beats due to “autonomic conflict”, rather than technical errors, might have contributed to the outbreaks of tachycardia.¹⁰

Limitations associated with conversion from ABV to blood flow were thoroughly studied by previous investigator.^{8,9,11,16} However, we cannot exclude the possibility that a Valsalva maneuver might have contributed to reduce venous return, and consequently, also to decrease CO and lower radial artery ABV during breath-holding since the test person changed position from sitting half upright to bending horizontally during AFI. Moreover, a change in arterial transvascular pressure cannot be excluded. However, since central venous pressure also might have increased correspondingly, the driving pressure gradient should remain (grossly) unchanged. This applies particularly to

Figure 4 Average blood velocity in the right vertebral artery vs time of a test person during steady state ergometer cycling. Arrows indicate start and stop of a period of apnea and face immersion (AFI) in ice-cold water.

the vertebral artery since hydrostatic pressure changes secondary to positioning changes expectedly were more pronounced in that vessel as compared with that of the radial artery. Since mean cerebral perfusion pressure, determined as the difference between mean systemic arterial pressure and right atrial pressure varied between 93 mm Hg and 128 mm Hg (during ergometer cycling and AFI) for the same experimental person in the heart catheterization study, we assume that cerebral perfusion pressure remained within the limits of cerebral blood flow autoregulation also in the present study.^{6,17} We also admit as limitations that we neither determined vertebral artery ABV during AFI in thermo-neutral water, nor during breath hold without face immersion, nor during face immersion while breathing via a snorkel. Previous investigators have shown that cerebral perfusion is maintained and even enhanced during cold stimulation of the face.¹⁸

Remaining in a position enabling free breathing while the body gradually cools until the heart stops, would seem advantageous for successful reanimation after drowning or avalanche. However, when breathing is inhibited, our findings suggest that apnea combined with exposure of the face to cold water will contribute both to decreased HR and redistribution of blood from the periphery to the central circulation, as shown in diving mammals. Our findings are supported by a report of young victims of drowning who were successfully resuscitated despite the fact that they were found floating with

their faces submerged and time to first contact with emergency service was median 121 (108–169) minutes.¹⁹

Conclusion

We suggest that the “diving response” combined with cold water stimulation of facial cold thermo-receptors and emerging hypercapnia and hypoxia increases cerebral blood flow during AFI. These mechanisms may well contribute to maintain cerebral oxygenation, and possibly, also induce faster brain cooling before cardiac arrest occurs in conditions of sudden airway blockade, thus, increasing the chances of surviving without neurological sequelae.

Ethics and Consent

When we carried out the heart catheterization study⁶ and the present pilot experiment in 1980, medical ethics committees were not established in our country and ethical approval was not required.⁷

Consent for Publication

The person who volunteered to serve as test person consented in publishing case details and the accompanying images.

International Medical Case Reports Journal

Dovepress

Publish your work in this journal

The International Medical Case Reports Journal is an international, peer-reviewed open-access journal publishing original case reports from all medical specialties. Previously unpublished medical posters are also accepted relating to any area of clinical or preclinical science. Submissions should not normally exceed 2,000 words or 4

published pages including figures, diagrams and references. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/international-medical-case-reports-journal-journal>
